Integration of Action and Language Knowledge: A Roadmap for Developmental Robotics

Angelo Cangelosi, Giorgio Metta, Gerhard Sagerer, Stefano Nolfi, Chrystopher Nehaniv, Kerstin Fischer, Jun Tani, Tony Belpaeme, Giulio Sandini, Francesco Nori, Luciano Fadiga, Britta Wrede, Katharina Rohlfing, Elio Tuci, Kerstin Dautenhahn, Joe Saunders, and Arne Zeschel

Abstract—This position paper proposes that the study of embodied cognitive agents, such as humanoid robots, can advance our understanding of the cognitive development of complex sensorimotor, linguistic, and social learning skills. This in turn will benefit the design of cognitive robots capable of learning to handle and manipulate objects and tools autonomously, to cooperate and communicate with other robots and humans, and to adapt their abilities to changing internal, environmental, and social conditions. Four key areas of research challenges are discussed, specifically for the issues related to the understanding of: 1) how agents learn and represent compositional actions; 2) how agents learn and represent compositional lexica; 3) the dynamics of social interaction and learning; and 4) how compositional action and language representations are integrated to bootstrap the cognitive system. The review of specific issues and progress in these areas is then translated into a practical roadmap based on a series of milestones. These milestones provide a possible set of cognitive robotics goals and test scenarios, thus acting as a research roadmap for future work on cognitive developmental robotics.

Index Terms—Action learning, humanoid robot, language development, roadmap, social learning.

I. INTRODUCTION

THIS paper proposes a developmental robotics approach to the investigation of action and language integration in embodied agents and a research roadmap for future work on the design of sensorimotor, social and linguistic capabilities in humanoid robots. The paper presents a vision of cognitive development in interactive robots that is strongly influenced by recent theoretical and empirical investigations of action and language processing within the fields of neuroscience, psychology, and cognitive linguistics. Relying on such evidence on language and action integration in natural cognitive systems, and on the current state of the art in cognitive robotics, the paper identifies and analyses in detail the key research challenges on action learning, language development, and social interaction, as well as the issue of how such capabilities are fully integrated. Although the primary target audience of the paper is the cognitive robotics community, as it provides a detailed roadmap for future robotics developments, the article is also relevant to readers from the empirical neural and cognitive sciences, as developmental robotics can serve as a modeling tool to validate theoretical hypothesis [35].

The vision proposed in this paper is that research on the integration of action and language knowledge in natural and artificial cognitive systems can benefit from a developmental cognitive robotics approach, as this permits the reenactment of the gradual process of acquisition of cognitive skills and their integration into an interacting cognitive system. Developmental robotics, also known as epigenetic robotics, or autonomous mental development methodology, is a novel approach to the study of cognitive robots that takes direct inspiration from developmental mechanisms and phenomena studied in children [37], [130], [262]. The methodologies for cognitive development in robots are used to overcome current limitations in robot design. To advance our understanding of cognitive development, this approach proposes the study of artificial embodied agents (e.g., either robots or simulated robotic agents) able to acquire complex behavioral, cognitive, and linguistic/communicative skills through individual and social learning. Specifically, to investigate action/language integration, it is possible to design cognitive robotic agents capable of learning how to handle and manipulate objects and tools autonomously, to cooperate and communicate with other robots and humans, and to adapt their abilities to changing internal, environmental, and social conditions. The design of object manipulation and communication capabilities should be

inspired by interdisciplinary empirical and theoretical investigations of linguistic and cognitive development in children and adults, as well as of experiments with humanoid robots. Such an approach is centered on one main theoretical hypothesis: action, interaction, and language develop in parallel and have an impact on each other; as such, the integrated development of action and social interaction permits the bootstrapping of cognitive development (e.g., Rizzolatti and Arbib [191]). This is possible through the integration and transfer of knowledge and cognitive processes involved in sensorimotor learning and the construction of action categories, imitation, and other forms of social learning, the acquisition of grounded conceptual representations and the development of the grammatical structure of language. In addition to advancing our understanding of natural cognition, such a developmental approach towards the integration of action, conceptualization, social interaction, and language can have fundamental technological implications for designing communication in robots and overcoming current limitations of natural language interfaces and human–robot communication systems.

This developmental robotics approach to action and language integration is also consistent with related brain-inspired approaches to mental development. For example, computational neuroscience approaches to cognitive development invoke the simultaneous consideration of neural development constraints and how these affect embodiment and cognition factors [134], [135], [259], [261], [264]. For example, Sporns [222] discusses in detail neurocomputational approaches to studying the role of neuromodulation and value systems in developmental robotics.

In short, a complete, embodied cognitive system is needed in order to develop communication skills. The array of skills that are necessary to achieve this goal spans the range from sensorimotor coordination, manipulation, affordance learning to eventually social competencies like imitation, understanding of the goals of others, etc. Any smaller subset of these competencies is not sufficient to develop proper language/communication skills, and further, the development of language clearly bootstraps better motor and affordance learning and/or social learning. The fact that the agent communicates with others improves the acquisition of other skills. By interacting with others agents receive more structured input for learning (imagine a scenario of learning about the use of tools). Generalization across domains is also facilitated by the ability of associating symbolic structures such as those of language.

To follow such a vision, it is necessary to aim at the development of cognitive robotic agents endowed with the following abilities.

- Agents learn to handle objects, individually and collaboratively, through the development of sensorimotor coordination skills and thereby to acquire complex object manipulation capabilities such as making artifacts (tools) and using them to act on other objects and the environment.
- Agents develop an ability to create and use embodied concepts. By embodied concepts, we mean internal states grounded in sensory-motor experiences that identify crucial aspects of the environment or of the agent/environmental interaction. Such concepts mediate the agents' motor reactions and are used in communication with

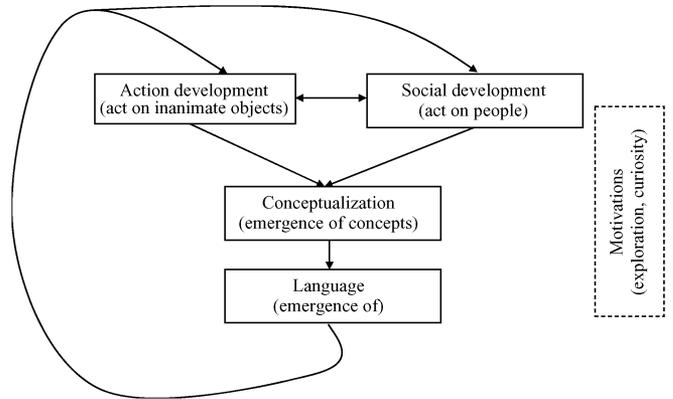

Fig. 1. Connections between the various skills of a developmental cognitive agent. The focus on this paper will be on the aspects more closely related to language and action development (boxes with continuous lines). The diagram also acknowledges the additional contribution of other capabilities related to motivation and affective behavior (dotted box), though they will not be part of the core discussion in this paper.

other agents. They can be organized in hierarchical representations, such as embodied semiotic schemata, used to plan interaction with the environment. Furthermore, embodied concepts can also be influenced through social and linguistic interaction.

- Agents develop social, behavioral, and communicative skills through mechanisms of social learning such as imitation. Interacting with other agents enables the agents to share attention on a particular object or situation in order to cooperate, and to benefit from social adaptation of the partner in order to learn new skills and acquire embodied concepts.
- Agents develop linguistic abilities that allow them to represent situations and to communicate complex meaning via language. They learn relationships between sounds, actions, and entities in the world. These relations will facilitate the discovery of word meaning and are a precursor to grammatical comprehension and production. More advanced communication skills develop based on the combination of previously developed embodied concepts and the development of symbolic and syntactic structures.
- Agents are able to integrate and transfer knowledge acquired from different cognitive domains (perception, action, conceptual, and social representations) to support the development of linguistic communication. The codevelopment, transfer, and integration of knowledge between domains will permit the bootstrapping of the agent's cognitive system.

The diagram in Fig. 1 gives an overview of the interaction and connection between the different capabilities. In addition to the focus on the development of action, social, categorization, and linguistics skills, the diagram also points at the important contribution of a motivational system.

Research on the further understanding and design of the above cognitive abilities in natural (children and adults) and artificial (robots) cognitive agents can be centered around the following four key challenges:

1) understanding how agents learn and represent compositional *actions*;

2) understanding how agents learn and represent compositional *lexica*;
3) understanding dynamics of *social* interaction and learning;
4) understanding how compositional action and language representations are *integrated*.

In the following section (Section II), we first provide a brief overview of the state of the art in experimental disciplines investigating embodied cognition and action/language processing in natural cognitive systems (humans and animals) and the state of the art in artificial cognitive systems (robots) models of language learning. This evidence on action language integration has important implications for the design of communication and linguistic capabilities in cognitive systems and robots [32], [38] to progress beyond the state of the art. Section III and Section VI will analyze in detail the specific issues on the four sets of key challenges respectively for action, language, and social learning, and for cognitive integration. Additional review of literature on the specific theoretical and empirical work on action, language, and social learning will be included within the key challenge Sections III–VII. This will further support specific claims and proposals for future developmental robotics investigations in the field. The paper then concludes with the presentation of the research roadmap and a description of key milestones.

II. RELATION TO THE STATE OF THE ART

A. Action and Language Processing in Natural Cognitive Systems

Recent theoretical and experimental research on action and language processing in humans and animals clearly demonstrates the strict interaction and codependence between language and action (e.g., Cappa and Perani, [39]; Glenberg and Kaschak, [85]; Pulvermuller *et al.* [183]; and Rizzolatti and Arbib, [191]). In neuroscience, neurophysiology investigations of the mirror neuron system [67], [76] and brain imaging studies on language processing provide an abundance of evidence for intertwined language–action integration. For example, Hauk *et al.* [99] used functional magnetic resonance imaging (fMRI) to show that action words referring to face, arm, or leg actions (e.g., to lick, pick, or kick) differentially activate areas along the motor cortex that either were directly adjacent to or overlapped with areas activated by actual movement of the tongue, fingers, or feet. This demonstrates that the referential meaning of action words has a correlate in the somatotopic activation of the motor and premotor cortex. Cappa and Perani [39] review neuroscience evidence on neural correlates of nouns and verbs. They found a general agreement on the fact that the left temporal neocortex plays a crucial role in lexical-semantic tasks related to the processing of nouns, whereas the processing of words related to actions (verbs) involves additional regions of the left dorsolateral prefrontal cortex. Overall, neuroscientific evidence supports a dynamic view of language according to which lexical and grammatical structures of language are processed by distributed neuronal assemblies with cortical topographies that reflect lexical semantics [182]. The mastery of fine motor control, such as nonrepetitive action sequences involved in making complex tools, is also seen as an ability related to the precursor of Broca's area in the modern brain, which is adjacent to the area that governs fine motor control in the hand. This is consistent with Rizzolatti and Arbib's [191] hypothesis that area F5 of the monkey's brain, where mirror neurons for manual motor activity have been identified, is homologous to a precursor of Broca's area involved in language processing and speech production and comprehension.

This neuroscience evidence is consistent with growing experimental and theoretical evidence on the role of grounding of language in action and perception [11], [85], [171]. Glenberg proposed that the meaning of a sentence is constructed by indexing words or phrases to real objects or perceptual analog symbols for those objects, deriving affordances from the objects and symbols and then meshing the affordances under the guidance of syntax. The direct grounding of language in action knowledge has been recently linked to the mirror neuron system (Glenberg and Gallese, in press). Barsalou [11] places similar emphasis on perceptual representation for objects and words in his "Perceptual Symbol Systems" account of cognition. For Barsalou, words are associated with schematic memories extracted from perceptual states which become integrated through mental simulators.

Developmental psychology studies based on emergentist and constructivist approaches (e.g., Bowerman and Levinson, [25]; MacWhinney, [132]; and Tomasello, [246]) also support a view of cognitive development strongly dependent on the contribution of various cognitive capabilities. They demonstrate the gradual emergence of linguistic constructs built through the child's experience with her social and physical environment. This is consistent with cognitive linguistics approaches (cf. Lakoff, [123]; Langacker, [124]) where syntactic structures and functions, that is, symbolic structures in both lexicon and grammar, are constructed in reference to other cognitive representations. For example, as the developmental stepping stones towards the emergence of abstract language and lexical categories are less well understood, one leading hypothesis is that abstract concepts bear metaphorical relations to (that is, are underpinned by) sensorimotor representations [123].

Another area at the intersection between developmental psychology and cognitive neuroscience that is relevant to cognitive and linguistic development is neuroconstructivism [185], [216], [263]. This theoretical and experimental framework puts a strong focus on the role of embodiment and brain codevelopment during cognitive development. It considers the constraints that operate on the development of neural structures that support mental representations and explains cognitive development as a trajectory emerging from the interplay of these constraints. This brain-inspired approach has also been supported by computational models, that have the potential to offer explanations of the interactions between brain and cognitive development [134], [135], [264].

All these studies on action–language integration have important implications for the design of communication and linguistic capabilities in cognitive systems and robots [32], [38]. Among the various approaches to design communication capabilities in interactive agents, some provide a more integrative vision of language and treat it as an integral part of the whole cognitive

system [33]. The agent's linguistic abilities are strictly dependent on, and grounded in, other behaviors and skills. Such a strict action–language interaction supports the bootstrapping of the agent's cognitive system, e.g., through the transfer of properties of action knowledge to that of linguistic representations (and vice-versa).

B. Action and Language Learning in Robots

Recent models from cognitive robotics research have addressed some of the issues described above, and contributed to the identification of the open research challenges in language and action research. Before we discuss in detail the key challenges, we review a few of the most interesting contributions.

Roy [200]–[202] propose the use of conversational robots able to translate complex spoken commands such us "hand me the blue one on your right" into situated actions. These robots are provided with a control architecture that includes a three-dimensional model of the environment (which is updated by the robot on the basis of linguistic, visual, or haptic input) and sensory-motor control programs. This model is consistent with the notion of schemas proposed by Piaget [174], in which the meaning of words is associated with both perceptual features and motor program. For example, the word "red" is grounded in the motor program for directing active gaze towards red objects. Similarly, the word "heavy" is grounded in haptic expectations associated with lifting actions. Objects are represented as bundles of properties tied to a particular location along with encodings of motor affordances for affecting the future location of the bundle.

Dominey, Mallet, and Yoshida [63] designed robotic experiments with robots that, in addition to reacting to language commands issued by the user (which trigger predesigned control programs), are able to acquire on the fly the meaning of new linguistic instructions, as well as new behavioral skills, by grounding the new commands in combinations of preexisting motor skills. This is achieved during experimental sessions in which the human user and a robot try to cooperatively achieve a shared goal. During these sessions, the interaction between the human user and the robot is mediated by two types of linguistic information: i) linguistic commands (e.g., "open right-hand," "take object-x," "give-me object-y," etc.) that trigger contextually independent or dependent behaviors; and ii) "meta" commands (e.g., "learn macro-x," "ok," "wait") that structure what the robot is to learn or regulate the human–robot interaction. In another experiment, Dominey and Warneken [64] designed robots able to cooperate with a human user by sharing intentions with her in a restricted experimental setting. This is achieved by allowing the robot to observe the goal-directed behavior exhibited by a human and then to adopt the plan demonstrated by the user. The robot thus shows both an ability to determine and recognize the intentions of other agents, and an ability to share intentions with the human user. These two skills are at the basis of social learning and imitation in humans, as proposed by Tomasello *et al.* [249]. These abilities have been realized by providing the robot with a model of the environment, the possibility to represent intentional plans constituted by sequences of actions producing specific effects,

and the ability to recognize actions and to attribute them to the robot itself or to a human agent.

Weng [260] designed a developmental learning architecture that allows a robot to progressively expand its behavioral repertoire while interacting with a human trainer that shapes its behavior. Different learning methods are used, including learning by demonstration (in which the robot learns while the trainer drives the robot's actuators), reinforcement learning (in which the robot learns through a form of trial and error process guided by the positive or negative feedback provided by the trainer), and language learning (in which the robot learns to associate the current sensory states to the action triggered by the trainer through language commands, and also learns to anticipate the next sensations and actions). The approach proposed by Weng is inspired by animal learning, neuroscience evidence, and cognitive science models, aiming to be general enough to be task independent (i.e., to allow the robot to learn any type of task through the same learning methods). This architecture has been successfully implemented, for example, in an humanoid robot that first learns to associate four language commands to four corresponding context-independent behaviors, then learns to associate a fifth language command to a composite action consisting of the execution of the four behaviors acquired previously in sequence (thanks to the mediation of the user that trains the robot by producing the four corresponding language commands after the fifth command), and (eventually) to be able to extinct one of the previously acquired reactions to language commands as a result of negative feedbacks provided by the user [279].

Sugita and Tani [233] developed a model in which a robot acquires the ability to both translate a linguistic command into context-dependent behaviors, and an ability to map sequences of sensory-motor state experienced while producing a given behavior into the corresponding verbal descriptions. More specifically a wheeled robot, provided with a two degrees of freedom (DOF) arm and a continuous time recurrent neural network (CTRNN) controller, is trained through a learning by demonstration method to carry out behavioral and linguistic tasks that consist respectively in: 1) interacting with the three objects presented in its environment, through the execution of three different types of behaviors such as "indicate object-x," "touch object-x," and "push object-x;" and 2) processing the corresponding language commands such as predicting the next word forming the corresponding sentence. The two tasks are carried out by two different modules of the neural controller. However these modules coinfluence each other through some shared neurons (called parametric bias) that are forced to assume similar states during the execution of the two related tasks. At the end of the training process, the robot shows an ability to translate the language commands into the corresponding situated actions, as well as an ability to generate the right language output when the robot is forced to produce a given behavior. The fact that the robot reacts appropriately to sentences never experienced during the training process, moreover, demonstrates how it is able to represent the meaning of words and the corresponding behavior in a compositional manner.

Steels, Kaplan, and Oudeyer have studied the acquisition of language in both developmental contexts (Steels and Kaplan,

[231]; Oudeyer and Kaplan, [168]) and evolutionary scenarios [226]. For example, Oudeyer and Kaplan [168] investigated the hypothesis that children discover communication as a result of exploring and playing with their environment, using a pet robot (Sony AIBO robot) scenario. As a consequence of its own intrinsic motivation, the robot explores this environment by focusing first on noncommunicative activities and then discovering the learning potential of certain types of interactive behavior. This motivational capability results in robots acquiring communication skills through vocal interactions without having a specific drive for communication.

The following sections will discuss in detail the key research challenges for cognitive robotics models of action and language integration, also referring to additional literature work addressing the specific research issues.

III. KEY CHALLENGE 1: LEARNING AND REPRESENTATION OF COMPOSITIONAL ACTIONS

The investigation of grasp-related functions in the brain and the successive discovery of the mirror neurons system have changed the perception of the importance of manipulation and its relationship to speech [191]. Although, the mirror neuron system is the quintessential example of this changed understanding of the neurophysiology of action, the study of the control of action in its entirety revealed modularity and compositionality as key elements of flexible and adaptable behavior generation [94], [152], [153], [194], [195]. The important point here is that areas of the brain that were considered as mere sensorimotor transformation circuits (i.e., changing coordinates or frame of reference) revealed a deeper structure with peculiar characteristics. This deeper structure includes multisensory neurons (e.g., visuo-motor in F5, visuo-haptic-proprioceptive in F4), generalization (the same neuron fires irrespective of the effector used), and compositionality (different areas specialize to different goals—reaching, grasping, etc.—rather than just reflecting a generic somatotopy). This is not a single homunculus, but rather multiple representations of the body with respect to the different action goals. Modularity was discovered in the cerebral cortex, but also down to the spinal cord. In a recent experiment [24], the so-called "motor resonance" effect has been demonstrated using the H-reflex technique of the peripheral nerves and transcranial magnetic stimulation (TMS). Additional experiments, such as those in Sakata *et al.* [203], showed a link between the "shape" of objects and the actions that can successfully manipulate these objects. Further, Gallese *et al.* [76] observed neurons in the premotor cortex (area F5), which fire selectively for certain combinations of grasp type and object shape (F5 canonical neurons). It seems that the brain stores a "vocabulary" of actions that can be applied to objects and the mere fixation of a given object activates potential motor acts even if, the monkey in this case, did not move.

This new evidence generated a surge of interest including the cognitive sciences on one side and, the robotics community on the other (see Clark [47] for a summary). Concepts like that of Gibsonian affordances started to be considered and modeled in robotics [141] and the links between imitation and manipulation were explored [142], [215]. In this respect, the link between

internal models, prediction, and the activation of a mirror-like system was approached in many different ways by using most disparate models ([106], [107], [170], to name a few). Clearly, this effort is even more relevant given the special relationship between mirror neurons, manipulation, and language [68]. In the experiment by Fadiga and colleagues [68], it was possible to measure motor effects when listening to words of different categories in strict congruence with the muscular activation required to pronounce the same set of words, which provides evidence for the presence of a speech-mirror system in humans akin to the grasp mirror system of the monkey. A more recent experiment confirms these findings and enters into the details of the motor resonance effect depending on the phonology versus the frequency of words [199]. The results indicate that rare words require a stronger activation of the premotor cortex as if the increased difficulty of the task requires reliance on the premotor activation and, conversely, common words are recognized because of a consolidated and larger number of cues which lower the premotor cortex activation.

Further, evidence has accumulated demonstrating the pervasiveness of this principle in several domains, including reaching (e.g., Graziano *et al.* [94]; Fogassi *et al.* [72]), attention [52] and motor imagery [108] to name a few. It remains to be considered that none of these skills is innate, but rather they develop through experience and in many cases require several years before reaching maturity [256]. Aspects like prediction (prospective behavior), and explorative and social motives have to be considered in motor learning since they seem to be crucial also for the engineering of adaptive systems in any meaningful sense. In this respect, it seems that newborns are sensitive to their own and other's motor movements and use these to assess social cues. For example, motion during eye gaze and human facial expressions are used in judging social interaction [69], [147]. Children use these early sensory commodities to bootstrap cognitive development, which includes motor skills. They subsequently go through an extensive period of exploration and development guided by various motivations (including the motivation of exercising the motor system, known as "motor babbling"). This leads to the acquisition of several motor skills like the ability of directing gaze, of coordinating head and eye movements, of coordinating gaze and attention together with reaching and eventually of manipulating the external world via grasping [256].

The motor control for articulation is a prerequisite for speech in humans, and it can be certainly considered as a prerequisite for speech also in artificial systems. This follows in some sense the approach of Liberman and Mattingly [126] who first formulated the so called "motor theory of speech perception," which was exactly proposed because of the difficulty of performing artificial speech recognition (ASR) entirely on acoustic analysis. Motor activation and sensory processing seem to be deeply intertwined in the brain (not only in the premotor cortex). Conversely, in robotics, it was possible to demonstrate an improvement due to learning in multisensory (sensorimotor) environments [101], [142]. Manipulation plays a pivotal role in this picture, sharing a similar "grammatical/hierarchical" structure with language, also owing to the close homology between F5 in the monkey and Broca's in humans, which further strengthen the link between action and language [191].

The next sections will highlight and discuss some of the main open research issues in action learning that are highly relevant to future cognitive robotics research. Specifically, the focus will be on: i) the properties of generalization and compositionality in action development; ii) the issues of recursive; iii) hierarchical motor representations; iv) the issues in embodied concept representation; and v) the mental representation of concepts during development. These research issues will then be used to identify specific milestones on action learning in the roadmap.

A. Generalization and Compositionality

The development of complex action and manipulation capabilities constitutes the foundation for the synchronous development of motor, social, and linguistic skills. For this, it is fundamental to identify the characteristics of action development that are compatible with this scenario and reject those that are mere engineering shortcuts. In particular, two core properties of biological motor control systems are considered: compositionality and generalization.

Compositionality refers to the ability of exploiting the combinatorial explosion of possible actions for creating a space of expressive possibilities that grows exponentially with the number of motor primitives. The human motor system is known to be hierarchically organized (with primitives implemented as low as at the spinal cord level) and it is simultaneously adaptive in recombining the basic primitives into solutions to novel tasks (via sequencing, summation, etc.). This hierarchy is implemented in the brain by exploiting muscle synergies, as well as other parallel controllers that reach different degrees of sophistication. These controllers either address the global aspects of a motor task, or the fine control required for the use of tools [192].

The aspect of generalization is equally crucial. Generalization refers, in this context, to the ability of acquiring (i.e., learning) motor tasks by various means, using any of the body effectors, and even via imagination of the motor execution itself (as for example in Jeannerod [108]). Naïvely, one could assume a common representational framework defined in some task independent system of coordinates. However, at the same time, neuroscience seems to be indicating that representation is effector-dependent [72]. This is clearly a question that needs to be addressed with links to many different aspects of the representation of linguistic constructs (e.g., actions versus the description of actions).

In artificial systems, this translates into the realization of a modular controller which, on the one hand, combines a limited set of motor primitives in realizing global control strategies, and on the other, learns to finely move single degrees of freedom to affect particular complex motor mappings (similar to what happens in the brain between the control effected by the premotor cortex versus that generated by the primary motor cortex). Simultaneously, the adaptation and estimation of bodily parameters must be considered both on the developmental and on the single task/session timescale. It is then particularly important that artificial systems show these properties if their motor controller has to form a suitable basis for further development in more higher-order cognitive scenarios such as language.

One interesting topic of research concerns the selection of a generic endpoint for subsequent actions (motor invariance) and fast adaptation to disturbances (changes in dynamics, weight, etc.). One example of flexibility in humans is the possibility of dynamically selecting the end point for subsequent tasks and reducing/increasing the number of degrees of freedom employed given the precision, noise, and other parameters required (e.g., imagine how humans reduce the number of degrees of freedom by laying objects on a table, or when precision is required such as in inserting a thread into a needle). This flexibility in choosing the effector to use seems fundamental to adaptability and relates to the existence of a peripersonal sensorimotor space [72]. Another example of flexibility in humans is in adapting to added perturbations (e.g., increased weight or changed dynamics). In the latter case, the motor system adapts after a few dozen trials and does it by estimating and modeling the change of dynamics maintaining a very energetically efficient control strategy (for example, see Lackner and DiZio [122]).

B. Recursive and Hierarchical Primitives

As previously pointed out, motor and linguistic skills share a relevant structure. Specifically, the modular organization of biological motor systems has been shown to be based on hierarchical recursive structures which have linguistic analogues in grammatical/syntactical structures.

Primitives have been identified in the spinal cord of frogs and rats, thus revealing that a modular structure exists at the movement execution level (the lowest level in the motor hierarchical structure). Interestingly, these modules have very simple combinatorial rules (linear superposition), which have led to interesting applications [268].

Higher hierarchical structures seem to play a crucial role in movement planning while still preserving a substantial modularity. As to this concern, there is evidence for the existence of individual cortical substructures which code increasingly higher movement related abstractions. There is evidence supporting the existence of structures coding: 1) hand kinematics [78]; 2) specific action goal, timing, and execution [193]; 3) movement sequencing (Carpenter [40], [41]); 4) virtual action descriptions (i.e., actions which do not have a concrete goal yet) [154]; 5) object affordance in terms of correspondences between object and motor prototypes [151]; and 6) movement recognition [76], [190].

At present, the rules governing the combination of different action executions have been widely studied and have been successfully applied in the area of motor control. Conversely, the rules governing the combination of goals in action planning appear to be more complex and not yet completely understood. Remarkably, these rules seem to be fundamental in order to fully exploit the properties of compositionality and generalization embedded in a modular architecture. Moreover, the "definition" (here to be understood as "development") of suitable compositional rules appears to be an ideal candidate for providing theoretical insights into the integration of action, social, and linguistic skills.

C. Hierarchical Learning

The observation that the brain uses hierarchical organizations in various sensory and motor systems has inspired the development of similarly organized artificial systems. Essentially, two

different approaches have been followed within this context: a bottom-up approach which falls within the mathematical framework of function approximation and a top-down approach based on the properties of the motor output.

As to bottom–up approaches, one of the first to mention is LeNet, which uses a convolution network with multiple layers for handwritten digit recognition [125]. More recently, Serre *et al.* [214] have developed a computational model of the lower levels of the visual cortex. This model alternates levels of template matching and maximum pooling operations, similar to the role of simple and complex cells as found in the visual cortex [105]. This model has shown excellent performance on immediate recognition benchmark problems, whereas extensions have been used for action recognition [109] and facial expression recognition [143]. The underlying principle of these systems is to gradually increase both the selectivity of neurons to stimuli along with their invariance to (2-D) transformations in a series of processing levels [81]. Further, the receptive field of the neurons increases along the hierarchy. In effect, these hierarchies serve to extract relevant features from the data stream and to combine these in compact, high level representations.

Besides having a biological foundation, hierarchical architectures are also believed to have computational advantages over single layered architectures. Hierarchical architectures trade breadth for depth and can theoretically achieve a logarithmic decrease in the number of neurons needed to learn certain tasks [18], [146]. However, hierarchical architectures are notoriously hard to train and may therefore not reach up to their full potential. Hinton *et al.* proposed a novel learning method for deep belief networks, which is a variant of a multilayered neural network, to address this problem [101]. In this method, each layer is trained separately to output a compact and sparse representation of its input distribution. Only the most relevant aspects of the input distribution remain at the top level, therefore facilitating generalization. If used in the opposite direction, i.e., from output to input, then each layer will attempt to reconstruct the original input from the compact output representation. An interesting direction for novel research is to apply these hierarchical learning methods for motor control.

In contrast to bottom–up approaches, top–down approaches are based on the input/output properties of the motor system. As to this concern, one of the most interesting theoretical results has been proposed by Wolpert in the framework of multiple paired forward and inverse models [268]. By devising a modular structure which has strong similarities with the modularity present in the cerebellum, it was proposed that multiple forward and inverse models can be simultaneously learnt in order to approximate complex sensorimotor mappings (module learning problem). Interestingly it was observed that the problem of choosing the correct subset of inverse models to handle the current context (module selection problem) can initially be solved by exploiting forward model predictions. Simultaneously, these predictions can be used to train suitable responsibility predictors which can be used later to solve the selection problem by exploiting contextual cues only.

New research in cognitive robotics should focus on the acquisition of hierarchical and compositional actions. Typical experimental scenarios might involve robotic agents that use pro-

prioceptive and visual information to actively explore the environment. This will allow agents to build embodied sensorimotor categories of object-body interactions. Actually, such trials have been demonstrated in [275]. It was shown that a humanoid robot can learn to generate object manipulation behaviors in a compositional way by self-organizing functional hierarchy by which the lower level primitives such as touch/lift/move objects are sequentially combined in the higher level by utilizing inherent time constant differences in the employed dynamic neural network model. However, the experiment was limited in its scalability and lacked developmental aspects. New studies should include more advanced experiments to look at developmental processes of acquiring manipulation action patterns based on combination and sequences of movements. For example, new robotics experiment might start from situations in which robot agent learns to use a tool (e.g., "stick") to push an object. Other tasks might include a cascade of interdependent actions, such as making a composite tool (e.g., combine a stick with a cuboid object—as with the handle and head of a "hammer") and using this tool on a third object (e.g., to crack open a spherical object—"nut"). Tasks can be inspired by object manipulation and tool making/use observed abilities in primates and humanoids, and their relationship with the development of linguistic capabilities (e.g., Corballis [50] and Greenfield [95]). A possible starting point could be to attempt object manipulation in order to get an agent to relate one object with another in a particular combination, as a young infant would [236]. In conjunction with the research undertaken by Hayashi and Matsuzawa [100] on the development of spontaneous object manipulation in apes and children, language experiments can focus on the following tasks: 1) inserting objects into corresponding holes in a box; 2) serializing nested cups; 3) inserting variously shaped objects into corresponding holes; and 4) stacking up wooden blocks. A first instance of the experiments could be able to isolate the agent from the human, so as to let it calibrate its joints and hand–eye coordination, recognizing color, form/shapes, and moving objects. The second part would be to introduce the agent to a "face to face" situation where a user would use linguistic instructions in order to expand the object "knowledge acquisition," taking the form of some kind of symbolic play.

D. *Embodied Learning of Representation and Concepts*

A fundamental skill of any cognitive system is the ability to produce a variety of behaviors and to display the behavior that is appropriate to the current individual, social, cultural, and environmental circumstances. This will require agents: 1) to reason about past, present, and future events; 2) to mediate their motor actions based on this reasoning process; and 3) to communicate using a communication system that shares properties with natural language. In order to do this, robots will need to develop and maintain internal categorical states, i.e., ways to store and classify sensory-motor information. To properly interact with the objects and entities in the environment, agents should possess a categorical perception ability which allows them to transform continuous signals perceived by sensory organs into internal states or internal dynamics in which members of the same category resemble one another more than they resemble members of other categories [97]. These internal states can be

called "embodied concepts" and can be considered as representations grounded in sensory-motor experiences that identify crucial aspects of the environment and/or of the agent/environmental interaction.

In the literature, there are two orthogonal approaches to representing concepts in artificial systems: one commonly known as the symbolic approach, the other as the subsymbolic approach. In the symbolic approach, conceptual information is represented as a symbolic expression containing recursive expressions and logical connectors, while in the subsymbolic approach concepts are represented in a continuous domain, for example, in connectionist networks or semantic spaces (cf. Gärdenfors [77]). Both approaches serve their purpose, but none seems to resonate well with human conceptualization. Humans use symbolic knowledge in representations for communication and reasoning [59], but these symbols are implemented on a neural substrate, which is nonsymbolic and imprecise. There have been few attempts to reconcile both, and new research should focus at the design of a conceptual representation which has the precision of logic symbols, but the plasticity of human concepts. This representation should also support the acquisition of concepts through embodied sensorimotor interactions.

Embodied concepts can be immediately related to sensory or motor experiences, such as motor action concepts or visual shape/object concepts, in which case we call them perceptual concepts. On the other hand, concepts can also be indirectly related to perceptual input, in which case we call them abstract embodied concepts (e.g., Wiemer-Hastings and Xu [265]; Barsalou [11]). These concepts are typically hierarchical constructs based on other abstract concepts and perceptual concepts. Categories are based on commonalities and structure of concepts that exists among items (cf. Rakison and Oakes [187]).

In line with a dynamical system view of cognitive development [239], embodied concepts should be conceived at the same time as prerequisites for the development of behavioral, social, and communicative skill and as the result of the development and codevelopment of such skills. In this respect, the development of embodied concepts might play the role of a scaffold which enables the development of progressively more complex skills.

An important challenge for cognitive robotics thus, consists in identifying how embodied agents can develop and progressively transform their embodied concepts autonomously while they interact directly with the physical and social environment (without human intervention), and while they attempt to develop the requested behavioral skills. This objective can be achieved through experiments studying different aspects of categorization and concept formation, with the goal of progressively integrating into a single setup categorization aspects previously studied in isolation. These experiments require that the robot is left completely free to determine how they interact with the environment in order to perform the categorization task. For example, a robot placed in front of objects (one at a time) varying with respect to their shape, size, and orientation will be trained for the ability to categorize the shape of the object by producing different labels for objects with different shapes. The robot will be rewarded on the basis of its ability to label the shape of the

object and will not be asked to produce any specific behavior (i.e., it will be left free to determine how to interact with the objects).

The goal of this research methodology is twofold. On one side, these experiments can pose the basis for the investigation of more complex experimental scenarios in which the development of an ability to linguistically categorize selected features of the environment will be integrated with the development of an ability to display certain behavioral and social skills. On the other side, these experimental scenarios can be used to study the role of active categorical perception and the role of the integration of sensory-motor information over time.

Active categorical perception refers to the fact that in agents which are embodied and situated, the stimuli which are sensed do not depends only on the structure of the environment, but also on the agents' motor behavior. This implies that categorization is an active process that requires: 1) the exhibition of a behavior which allows the agents to experience the stimuli that provide the necessary regularities to perceptually categorize the current agent/environmental state; and 2) the development of an ability to internally elaborate the experienced sensory states. The ability to coordinate the sensory and motor process, however, does not only represent a necessity but also an opportunity, since the possibility to alter the experienced sensory stimuli might significantly simplify the perceptual categorization process or might lead to the generation of the regularities that are necessary to perceptually categorize functionally different agent/environmental situation. The goal of this set of experiments, therefore, should be that to identify how such a possibility can be exploited. Although pioneering research in this area has provided important theoretical contributions [44], [114], [161], [165], [173], [212], as well as few preliminary demonstrations of how artificial embodied agents can develop active categorization skills [13], [160], [162], some themes still deserve substantial further investigations. In particular, open questions concern: i) the identification of the modalities with which action can facilitate or enable categorical perception; ii) the identification of how internal categories can be represented; and iii) the identification of the adaptive mechanisms which can lead to the development of two interdependent skills (the ability to act so to favor categorical perception and the ability to categorize perceived sensory-motor information codetermined by agents' motor behavior).

Another important focus of future research on embodied concept learning and representation regards the development of abstract perceptual categories based on regularities distributed over time. The regularities that can be used to categorize functionally different agent/environmental circumstances are not necessarily available within a single sensory pattern and often require an ability to integrate sensory-motor information through time. Consider, for example, the problem of grasping objects of different shapes on the basis of tactile information or the problem visually recognizing an object by visually exploring it through eye movements. To functionally categorize the nature of these agent/environmental situations, the agent should take into account aspects such as the duration of an event or the sequence with which different events occur. This problem is further complicated by the fact that regularities that should

be integrated over time might be distributed at different time scales (e.g., ranging from milliseconds, to seconds or minutes). Recent research in this area has demonstrated how robotic agents can successfully develop categorization abilities and abstract perceptual categories provided that certain prerequisites are met [13], [82], [106], [107], [163], [233], [237], [268], [275]. These studies also provide useful hints which might help us to identify the characteristics of the developmental process and of the robots which represent a prerequisite for the ability to develop abstract concepts. However, whether and how these models can be scaled to more complex scenarios remains an open question which deserves further investigations.

E. Social Learning of Concepts

In order to understand how humans represent knowledge, much can be learned from studying how infants and young children acquire concepts. There are many experimental studies and theories on concept acquisition in young children [187]. Children, for example, employ a number of strategies to facilitate concept acquisition, such as mutual exclusivity, where a word is only related to one object in a context and not to others [136], or the preference to bind unfamiliar words with unfamiliar perceptual input: the novel name novel category principle [140]. Also, language seems to play a crucial role in concept acquisition. Although linguistic relativism—the interaction between language and thought—used to be controversial, recent studies have convincingly shown that language and conceptualization do interact in a number of different domains, such as time, space, and color (for example, [23], [83], [96], [196], and [266], but see Pinker [177] for a critical note). Although the evidence for the interaction between language and concepts is convincing, it is only recently that the importance of language for the acquisition of concepts has been noted. Choi *et al.* [45], for example, show how young children (18–23 months) are already sensitive to linguistic concepts for space (see also Majid *et al.*, [133]). This does not tell whether children actively use language to acquire concepts. However, Xu [274] shows how nine-month-olds' use of language can play an important role in learning object concepts, and more recently, Plunkett, Hu, and Cohen [178] show how linguistic labels play a causal role in concept learning of 10-month-olds.

In the tightly controlled experimental settings of above mentioned psychological studies, children are exposed to unidirectional communication: objects and linguistic labels are presented to the infants and they induce concepts from these experiences. These experimental conditions, however, do not reflect reality, where children and caretakers engage in a rich interaction with joint attention, referential and indexical pointing, and implicit and explicit feedback. It is expected that rich, cultural interaction is essential to cognition [243]. New research should explore the influence of rich interaction on the mental development of robots. It has been argued and, to a certain extent, it has been experimentally shown that this tight interaction is bimodal, involving both language and action and that this occurs from an early age. Locke [129] reports how 16.5-month-old infants significantly join vocalizations and referential points, which would suggest an integrated system.

Concerning the mental representation of categories and concepts, it is important to first distinguish between categories and concepts. For the pragmatic purposes of developmental robotics and cognitive systems, categories are seen as directly related to perceptual experiences and concepts as higher-level representations, based on categories, but possibly also deduced from contextual information without necessarily being related to perceptually grounded categories. Categorization in artificial intelligence and by extension in recent cognitive systems work has often been considered to be a supervised learning task (e.g., Ponce, [179]), whereby pairs of stimuli (often images) and labels are offered to a learning algorithm. In recent years, progress has been made in the representation of images, using either local or global features, and in the learning algorithms. However, nearly all focus on passive learning of categories and concepts from annotated data (cf. however [167]). Future research in developmental robotics could explore active learning, in which the learner (in this case the robot or cognitive system) engages in a dyad with its caretaker and actively invites the caretaker to offer it learning experiences while, at the same time, using the caretaker to refine categorical and conceptual knowledge. This is an extension of classical symbol grounding (see Harnad, [97]). Instead of meaning only being defined in perception of objects in the environment, social and cultural interaction has an equally important influence on meaning. This is known as extended symbol grounding [17]. The cultural acquisition of categories has been explored in simulation and robotic environments (see, for example, Steels, [227] and Vogt, [254]) and close parallels have been noted between simulated cultural learning of words and categories and human category acquisition [16], [230]. However, while extended symbol grounding has not been explored in environments involving both humans and robots (although see Roy, [201] and Seabra Lopes and Chauhan, [213]), this offers an exciting opportunity for cognitive systems research, with a possible impact on other disciplines, such as semantic web research and information search technology.

IV. KEY CHALLENGE 2: LEARNING AND REPRESENTATION OF COMPOSITIONAL LEXICONS

In this section, we outline what we see as the most important challenges for automatic language learning in cognitive robots. Amongst the various aspects and level of analyses of language (e.g., phonetics, lexical-semantic, syntactic, and pragmatics), the discussion below will mostly focus on the issues related to the acquisition of meaning and words and the developmental emergence of syntactic constructs. This restricted focus is justified by the main aim of the paper on the modeling of lexicons acquisition in developmental robots. We begin with a necessarily brief sketch of what needs to be modeled, drawing on state-of-the-art accounts of language acquisition in cognitive linguistics and developmental psychology (Section IV-A). In Section IV-B, we turn to the question of how these findings can inform experimental research in developmental robotics. Section IV-C then presents theoretical and experimental issues on acoustic packaging of action and language knowledge in robot-directed speech, as well as adult- and child-directed speech.

A. Language Acquisition: Insights From Linguistics and Psychology

Recent empiricist approaches to language acquisition (cf. Tomasello [246] and Goldberg [89] for surveys) have amassed considerable evidence that natural languages may be learnable without the aid of substantial language-specific cognitive hardwiring ("Universal Grammar"). Key findings of this "usage-based" approach to language acquisition relate to the following:

- the crucial role of general cognitive skills of cultural learning and intention reading;
- the grounding of language in both sensorimotor embodiment and social interaction;
- the significance of statistical learning and the distributional structure of children's linguistic input;
- the item-based nature of early child language;
- the gradual emergence of grammatical abstractions through processes of schematization.

Given a sophisticated capacity for statistical learning (cf. Gómez [92] for a recent review), as well as the peculiar structural properties of the specialized linguistic input that they receive [175], [218], children are assumed to acquire complex compositional grammars through piecemeal schematizations over a massive body of memorized and categorized chunks of linguistic experience. Grounded in a set of specifically human skills of social cognition ("shared intentionality;" cf. Tomasello *et al.* [249]) and closely interwoven with aspects of general cognitive development, the emergence of grammar is thus described as a slow and gradual transition from rote-learning lexical formulae (holophrases) to increasingly abstract (pivot schemas, item-based constructions), and ultimately fully schematic grammatical resources (abstract constructions, i.e., maximally generalized morphosyntactic rules). Syntactic categories of adult language (e.g., "determiner," "verb phrase," "infinitival complement clause," etc.) are assumed to have no correlate in early learner grammars, but only to arise during ontogeny (contrary to the "continuity assumption" of nativist linguistic theories; cf. Pinker [176]). Strictly speaking, it is in fact not assumed that the learning process ever reaches an unchanging "final state" at all—instead, linguistic knowledge is seen as constantly adapting to experience, and it is not assumed that speakers will always extract the highest conceivable generalizations from the data [54], [277]. The coexistence of massive regularity and, likewise, massive residual idiosyncrasy in the system points to a cognitive architecture that redundantly represents both entrenched linguistic exemplars (memorized tokens of linguistic experience that are sufficiently frequent) and schematizations over such exemplars (as "emergent" generalizations that are immanent in a set of stored instances), thus spanning a continuum from concrete lexical to abstract grammatical structure in a unified representational format [1], [29]. Crucially, due to the assumed tight feedback loop between speakers' linguistic experience and the elements and structure of their internalized linguistic systems, quantitative-distributional properties of the input take centre stage in usage-based approaches to language acquisition.

We suggest that research in cognitive robotics should capitalize on this important aspect of the learning problem for the design of psycholinguistically informed experiments. Specifically, the design of learner input for such experiments should accommodate the following relevant insights into structural properties of child-directed speech (CDS): the linguistic input that children receive is considerably less variegated (i.e., it uses fewer words and constructions than speech directed at adults; cf. Cameron-Faulkner *et al.* [31]), it is highly stereotypical (words and constructions are used in their most common senses/functions; cf. Karmiloff and Karmiloff-Smith [113]), it is heavily redundant (i.e., strongly repetitive and reformulative; cf. Küntay and Slobin [121]), and also distributionally skewed in terms of word-construction-combinatorics (i.e., abstract constructions are familiarized via disproportionately heavy use of a single prototypical verb in the pattern; cf. Goldberg *et al.* [90], Zeschel and Fischer, [278]). At the same time, when it comes to the core question of precisely how and exactly when specifically which kinds of abstractions are formed during language development, many details of learning-based approaches to language acquisition are as yet unresolved. For instance, are generalized constructional schemas only formed after an initial item-based phase of syntactic development, and possibly only after a certain critical mass of relevant "verb islands" has been acquired [4], [241]? Or are there "weak" representations of such generalizations from very early on in development that just need to accrue salience before they can be evidenced in learner productions [2], [139], [247], or primitive semantic structures to be found in CDS that correspond in some way to the grammatical constructions that are to be learned (Tellier, [238]; Fulop, [75]; Sato and Saunders, [204])? Is there a facilitating effect of semantic similarity on schema formation [148], [244]? Or is transfer of learning in syntax purely form-based [158], [159]? It is by modeling such issues in appropriately designed artificial learners that future simulation studies and grounded robotic experiments that permit a systematic manipulation and full control of all supposedly relevant variables can make a unique contribution to language research within developmental science.

B. Application to Automatic Language Learning

Since the 1990s, there has been a sea change towards the use of statistical, corpus-based methods in all areas of computational linguistics, including the computational modeling of language acquisition. Work in this field constitutes a relatively recent addition to the methodological repertoire of developmental science (cf. Cartwright and Brent [42]; Elman [66]; Kaplan *et al.* [112]), and it has provided support for several important tenets of usage-based theories of language and its acquisition (cf., e.g., Solan *et al.* [219]; Borensztajn *et al.* [22]; Alishahi and Stevenson [5]). Also in the community of theoretical computational linguistics, which had traditionally seen the grammar learning problem to be intractable without universal grammar in view of Gold's results [88], biases in the data such as typically found in CDS are beginning to be recognized as factors that ameliorate learning difficulty [3], [48], [66]. However, the algorithms which such approaches use to distil grammars from corpora are usually not only semantically

blind, but also provided with certain grammatical information from the outset (e.g., part-of-speech annotation). From a developmental perspective, neither of these two features carries over to human learners—children ground linguistic signs in embodied experience, and they are not assumed to be equipped with adult syntactic categories such as "preposition" or "conjunction" from birth. Moreover, early caretaker–child interaction is restricted to joint attention scenarios [65], which is a further property that lacks in these approaches.

By contrast, language research in cognitive robotics (e.g., Steels [224]) not only seeks to ground linguistic symbols in aspects of agents' sensorimotor experience, but also recognizes the need to address various social-cognitive and interactional underpinnings of the learning scenario (such as joint attention or perspective taking) that are beyond the scope of purely structure-oriented approaches to grammar induction from linguistic corpora. Regarding the present focus on the emergence of compositionality from holophrastic formulae, previous research (e.g., Sugita and Tani [233]) has already provided successful demonstrations of small-scale versions of this task: much in the same way that children learn to use holophrases like "lemme-see!" to express complex meanings like "show me this object that we are jointly attending to," robot learners can come to associate internally complex utterances with concurrently experienced perceptual-motor patterns, and subsequently break these patterns down to different formal and semantic constituents in a distributionally driven "blame assignment" process of the type also ascribed to child language learners [246]. However, the compositional patterns acquired in previous robotic experiments on grounded learning are extremely simple and bear little resemblance to natural language grammars. Put differently, robot learning of holophrases with subsequent decomposition and generalization of an underlying argument structure construction constitutes an important prerequisite for higher-order grammar learning, but it is not the ultimate goal in itself. Key challenges that remain to be addressed on the way to truly naturalistic and successful (i.e., quasihuman-like) language acquisition can be grouped into three categories.

- Social complexity: ultimately, all linguistic skills should be learned in an unsupervised manner from naturalistic social interaction with human communication partners, thus requiring a working implementation of various prelinguistic (i.e., language-independent) pragmatic prerequisites for human ostensive-inferential communication [221], [249].
- Linguistic complexity: ultimately, the system should be able to reanalyze learned expressions as a compacted encoding of many grammaticalized dimensions in parallel (e.g., participant structure, tense, aspect, voice, mood, polarity, information structure, number, case, definiteness, and reference tracking/binding to name a few), and to combine the ensuing multilayered representations iteratively to produce and interpret progressively more complex (recursively embedded) syntactic structures.
- Quantitative complexity: ultimately, the learning target should approximate the statistical structure of natural languages as they are actually experienced by a human learner, thus taking experiments from restricted laboratory settings involving just a handful of lexical items and even

fewer grammatical patterns to essentially open-ended massive noisy input with naturalistic distributional properties.

For the moment, these objectives remain long-term goals that are beyond the scope of current experiments on grounded language acquisition. In fact, some researchers are skeptical that higher-order grammar learning along these lines can be achieved with current neural network technology at all [226], [229] and advocate the use of symbolic grammar architectures such as fluid construction grammar [(FCG); Steels [225]] and embodied construction grammar [(ECG); Bergen and Chang [19]] instead. However, if the initial focus is on the emergence of compositionality in language, action, and action-language mappings, reliance on these mechanisms that include them cannot be built into the system as a design principle already, and any language-specific parameterization on which the learning should take place should not be presupposed and should generally be minimized as far as possible.

In sum, the logical next step thus consists in combining learning scenarios to allow for learning on the basis of distributional cues yet connected to real-world, embodied experience. The first major challenge involved is thus, the development of a suitable learning architecture that allows grammar induction from large amounts of linguistic data that are connected to categorized patterns of sensory-motor experience. It should permit the representation of constructional exemplars both as records of particular observed linguistic tokens and as records of previous successful analyses of these tokens (as implemented in symbolic approaches such as Batali, [12]). In addition, learners must be capable of mapping recognized individual elements in a string, as well as properties of their sequential configuration to representations of objects, events, and relations obtained from sensory-motor processing. The second major challenge then relates to the identification of suitable reduced-complexity learning scenarios and interactional tasks for robot language learning experiments that nevertheless accommodate relevant properties of the corresponding real-life challenge that children are facing. Starting out from corpus-based identifications of statistical properties of CDS that permit child language learners to extract the system underlying their earliest productively assembled multiword combinations from the input, useful operationalisations/adaptations of these properties for the necessarily more restricted input of robots in grounded language learning experiments must be devised. Finally, a third major challenge for future research relates to the implementation of various social-cognitive and interactional prerequisites for child language acquisition in which the process of grounded distributional grammar learning is embedded. These include learners' preestablished understanding of the triadic structure of interactions between two interlocutors and an object that is being jointly attended to [41], [240], [242], their understanding of the behavior of others as intentional [14], [15], [40], [249], their understanding of the normative structure of conventional activities such as symbolic communication [188], [189], and their awareness of the cooperative logic of human communication [127], [128], [248]. Especially when scaling up from highly restricted experimental settings to learning from more natural kinds of social interaction, the definition of useful operationalisations of these prerequisites constitutes a further

important issue on the agenda of automatic language learning research.

Steels [225], [226] has recently proposed a model of evolutionary stages in the complexity of human language that provides a clear operational definition of qualitative changes in language development that can be easily tested in robotic experiments. If the above challenges are met, it is not only possible to systematically investigate the transition from holophrases to simple compositionality (stage III) in embodied, interactional experiments, but also from sequentially unordered multiword speech to the item-based constructions of a syntactically structured grammatical language (stage IV) and ultimately to the abstract constructions of Steel's stage V-languages (higher-level constructions encoding the structural systematicity and internal coherence of a grammatical system at large). By investigating these issues along the lines of (and with special attention to unresolved questions in) current usage-based models of language acquisition in linguistics and psychology, such results promise to be of interest also to developmentalists outside the narrower field of cognitive robotics.

C. Acoustic Packaging

In developmental research, it has been recently shown that infants can use speech also as a signal structuring visual input. Brand and Baldwin [26] suggested a tight interaction between speech and actions calling it "prosodic envelopes." This term refers to segments of both, the action and speech stream that reliably coincide. An example would be that important points in the action stream might be highlighted in the speech stream by a change in prosody or a break in an ongoing stream [26]. This idea that the presence of a sound signal helps infants to attend to particular units within the action stream was originally proposed and termed acoustic packaging by Hirsh-Pasek and Golinkoff [103]. The authors argue that infants can use this "acoustic packaging" to achieve a linkage between sounds and events (see also Zukow-Goldring, [280]) and to observe that certain events cooccur with certain sounds, like for example, a door being opened with the word "open!" In fact, recently, many authors highlight the benefit of words or labels as signals that highlight the commonalities between objects [258] and situations [45], facilitate object categorization [10], [274], have the power to override the perceptual categories of objects [178], and reason about physical events [79]. Thus, specific sound patterns and categories or types of sound patterns are suggested to help infants to get a better sense of the units within the action stream on the one hand. On the other hand, the accompanying action provides pragmatic power to the linguistic information making it more perceivable and thus, bootstraps language learning processes. In this vein, Gogate and Bahrick [87] showed that moving an object in synchrony with a label facilitated long-term memory for syllable–object relations in infants as young as seven months. By providing redundant sensory information (movement and label), selective attention was affected [87]. However, Zukow-Goldring and Rader [280] remind us that synchrony does not always refer to simultaneous occurrence, and that the exact parameters and theoretical background

for the notion of synchrony have to be developed in order to understand how nonlinguistic and linguistic information is linked. In this point, it is of interest to investigate the following.

- How the speech stream overlaps with the action needed to fulfill the task, i.e., which parts of the motions are highlighted by what aspects of speech?
- How is the velocity profile of the action during the performance of the task and does the velocity differ when speech accompanies a motion?
- How do the intonation contours of the speech stream correlate with the action, i.e., when the contours are raising, is there also an up-motion noticeable and which parts of the motions are prosodically highlighted, e.g., by falling or raising contours?
- Do the pauses in both channels (speech and motion) coincide?

V. KEY CHALLENGE 3: SOCIAL INTERACTION AND LEARNING

Traditional approaches for the study of communication and learning are based on a metaphor of signal and response [73]. Recently, however, interactive and social aspects of learning have been emphasized (, Nehaniv and Dautenhahn, [155]). Accordingly, for language to emerge, a learner—even when not fully able to signal and respond appropriately in an interaction, like a child that does not yet speak or, as investigated in human–machine interaction, a robot that does not function smoothly (Wrede et al., [272])—needs to treated as a partner, to which the other participant will attempt to adapt. Thus, de León ([57]) emphasizes that children "by the time they begin to speak, they have already 'emerged' as participants." In this section, we pursue topics that focus on the learning processes within the context of social interaction. It is becoming increasingly clear that children's conceptualization of the external world and their language system are scaffolded by interaction partners who adapt to them [269].

What does this approach mean for a robot that is supposed to learn action and language? Imagine a child that sees a round thing that can roll. Adults call it "ball." What then gives the child a basis for assuming that that "ball" refers to the object and not to the action of rolling? For a long time, this central challenge of language acquisition had been explained in terms of mapping: a word typically has to be mapped either to an object, an action, or a relationship that holds amongst them. This mapping mechanism suggests a link, but does not solve the question how the link is actually achieved. As already pointed out by Quine [186], it is not clear how a child can achieve such mapping, because it is not the case that a child can fully rely on inner mechanisms allowing her or him to map the correct referent (an object or an action) onto a word. In addition, once a link between, e.g., an object and a word is established, it is dynamic and can be changed (extended or specified) in the course of further experience. For example, children may map the word "ball" to the action of rolling, but can define it more precisely later. Tomasello [245] attacks the metaphor of mapping as false and suggests instead that learning is not only about cognitive achievement but also about embodied social interaction, in which a person uses a symbol for the purpose of redirecting another person towards

the entity that is referred to. Moreover, children understand intangible situational concepts such as "sleep" or "breakfast" from a very early age [246]. In this social approach, it is not only the word that is the sole information available to the hearer for the resolution of reference. Also the behavior of the speaker and the circumstances of the situation, as well as the hearer's experience contribute to the formation of the concept [56], [198], [245]. This permits the investigation of different forms of learning and scaffolding processes that help a learner to resolve reference in an interaction. Since human behavior is variable, scaffolding as a form of tutor behavior varies across persons. This variability causes problems in artificial systems that are expected to react appropriately to, for example, any form of showing an object (like pointing to it, holding it, or waving with it) and to learn from examples that differ in certain aspects. New research should focus on the identification of different forms of the tutoring behavior, and then to seek for stability, i.e., structure on different levels of analysis. As conversational analysis shows [93], [211], the variability of human behavior in interaction can be assessed by discerning more general principles of communicational organization such as turn taking behavior. It is our goal to investigate such principles of organization in order to cope with variability in multimodal behavior.

Nevertheless, as for children, a robot's acquisition of language will necessarily reflect many characteristics of the linguistic behavior of those particular persons with whom it interacts [205]. Many properties of language development comprise evidence of mechanisms consistent with recent research in neuroscience proposing dual pathways, dorsal and ventral, e.g., in processing of articulation versus processing of meaning (Saur, [209]). For instance, before they are able to use language to manipulate the intentions of others in the social world around them, infants are already learning to recognize word forms through interaction with their carers [234]. Moreover, the roles of mechanisms of intersubjectivity [250], [251] such as timing, turn-taking, or joint attentional reference [246] will scaffold and shape language acquisition in a social context.

The next sections will look at some of the most important issues in social learning and interaction in cognitive robots. In particular the focus will be: 1) contingency and synchrony in social interaction; 2) cognitive architectures for intermodal learning; 3) the scaffolding of behavioral, linguistic, and conceptual competencies through social interaction; and finally 4) a list of the main open research challenges.

A. Intermodal Learning: Contingency and Synchrony

Our perspective on developmental learning is based on the idea that learning is driven primarily through interaction with persons as well as the ambient environment [206], [207], [273]. This idea is supported by Csibra and Gergeley [53], and Zukow-Goldring [280], who state that learning through imitation is limited because the observed action does not always reveal its meaning. First-person experience as well as social scaffolding may be necessary to acquire certain behavioral competencies [207]. In order to understand an action, a learner will typically need to be provided with additional information given by a teacher who demonstrates what is crucial: the goal, the means and—most importantly—the constraints of a task

[280]. The tutor, on the other hand, has to make sure that the learner is receptive, and thus ready to learn. They both follow certain interactive regularities. Such interactive rules have been assessed in terms of "grounding" (e.g., by Clark [49]) on a more abstract level, but also in terms of "turn-taking" or "contingency" on a more perceptual level. With this sequential organization of an interaction, more systematicity can be derived from the variability of the behavior.

Clark [49] provided one of the first grounding models with the claim that every individual contribution to a discourse has to be registered by the listener; that is, the listener has to provide a signal of understanding in order for both participants to add the content to their pool of commonly shared information and beliefs ("common ground"). On a more perceptual level, the term contingency refers to a temporal sequence of behavior and reaction, and it has been shown that it plays an important role in the process of developmental learning (e.g., Kindermann, [116]; and Markova and Legerstee, [137]). In the literature, there is an agreement that contingency is an important factor in the cognitive development of infants—as researched, e.g., within the still face paradigm (e.g., Tronick *et al.*, [252] and Muir and Lee, [150]). There is evidence that parents intuitively produce contingent actions, e.g., mothers have been shown to decrease their level of contingency with their infant's increase of development for a certain task [116]. Infants have been shown to develop a sensitivity to contingent interactions around three months of age [232], and typically by the middle of the first year infants begin to move from canonical babbling towards syllable production related to their carers' speech [253]. This development is rooted in contingent interactions with adults. On this basis, infants not only detect contingency, but also expect and try to elicit it [166]. Thus, infants prefer persons who are and have previously been interacting contingently with them [20].

Against this experimental background, we argue that in order to pursue a social interaction, a system needs to be equipped with mechanisms that detect and produce contingent behavior. Tanaka and his colleagues [235] have shown that when a system produces a contingent behavior, it gains more attention. The authors provided such a system to kindergarden children and found out that toddlers socialized with this system for a sustained period of time. This suggests strongly that the capability of producing a contingent behavior facilitates human–robot interaction. Yet, for a system to learn form a human, it is necessary that it not only can produce contingent behavior but also detect it. This can be achieved in gathering features that tutoring behavior exhibits in different modalities [197]. These features will guide the development of tutoring spotter for human–robot interaction systems. This will enable the system to pay attention to an ostensive action and the crucial parts or circumstances, which is helpful in resolving the question of what and when to imitate [156].

Mechanisms that detect (and produce) contingency can be a precursor of later dialogical competencies as described in the framework of grounding. While contingency mainly describes a temporal pattern, where one event occurs as an answer to a previous one, grounding relies on semantic information in the sense that one event (or speech act) needs to be grounded by an interaction partner through a signal of understanding.

In recent developmental research, the problem of grounding a symbol has been assessed by analysing intersensory relations between multimodal signals. The idea is that, e.g., words as acoustically perceived signal and actions as visually perceived signal may become paired by the shared temporal synchrony [9]. In experimental settings, infants have been shown to learn a label for a new object more easily when the verbal referent was uttered in synchrony with a movement of the named object. In contrast, the name of an object being moved out of sync was not learned [87]. While temporal synchrony has been described as a means to provide "invariance," at the same time it is important to analyze the variability of the tutor behavior in order to better understand how tutors structure their actions towards infants. Here, we follow the idea of "acoustic packaging" (see Section IV-C of this paper) that has been pushed forward in experimental work by Brand and Tapscott [27]. Following Hirsh-Pasek and Golinkoff [103], they suggested that acoustic information, typically in the form of narration, overlaps with action sequences and provides infants with a bottom–up guide to find structure within events. Brand and Tapscott's [27] results support this idea indicating that infants appear to bind sequences of (sub)actions together based on their cooccurrence with speech. That is, given an action sequence and a verbal utterance overlapping with only part of this sequence, infants are likely to interpret only those action sequences as belonging together that fall within the range of the verbal utterance.

B. Intermodal Learning Architecture

Synchrony and contingency are two of the fundamental phenomena in tutoring and social learning. While there is a growing body of research on the phenomenon of synchrony, there exist only few models of synchrony on an artificial system (Prince *et al.*, [181]; Kose-Bagci *et al.*,[117]; Broz *et al.* ,[28]; Rolf *et al.*, [198]). Based on current results reported in literature, models have to address the following questions.

- What is synchrony (in terms of a higher level and temporal structure as well as correlation measure) (Definition)?
- What are the entities that synchrony works on (Segmentation)?
- How can it be detected in the interaction (Recognition)?
- What functions does it serve (Model)?
- How does it vary in different speakers with their way of "acoustic packaging" and different situations (Analysis)?
- What is the role of the different modalities (e.g., does vision provide primarily spatial information whereas auditory synchrony is more related to temporal structure?) and how do they interplay?

Currently, the scientific debate (Workshop on Intermodal Action Structuring, in ZiF, Bielefeld in July 2008) seems to converge towards a consensus that the important criteria for synchrony are: 1) temporal cooccurrence of an event in different modalities; and 2) a correlation between the characteristics of these events. In contrast, "inverse synchrony," meaning that events in two modalities show a temporally exactly disjunct distribution—such as a sequence of speech being followed by a speech pause with a sound of noise that is deliberately being framed by the tutor's utterance—does not constitute an instance of synchrony but rather describes the characteristics of causality or—within the context of interaction—contingency.

The importance of contingency has been recognized by computer scientists and there exist already some computational models for contingency (e.g., Movellan [149] and Di Paolo *et al.*, [61]). However, these models tend to be focused on a single modality and rigidly limited to specific concrete applications where an "event" has been clearly defined (e.g., Auvray *et al.*, [8]). In order to foster research with respect to developmental learning on robots, the following questions need to be addressed in the near future.

- What is contingency (in terms of temporal structure as well as with respect to semantic content, if any) (Definition)?
- What are the entities that contingency works on (Segmentation)?
- How can contingency be detected in the interaction (Recognition)?
- What functions does it serve (Model)?
- How is it related to further sequential organization of interaction such as turn-taking (Analysis)?
- What is the role of the different modalities and how do they play together?

Against this background knowledge about synchrony and contingency within the framework of developmental robotics, the question of how these two phenomena are interwoven can be tackled. Our current hypothesis is that in order for an infant to learn new actions she or he can rely: 1) on structured information provided by the tutor through the application of synchrony as well as acoustic packaging; and 2) on grounding on a more semantic and contingency on a more perceptual level.

Since we assume a continuous mutual adjustment (e.g., Fogel and Garvey [73], and Wrede *et al.* [273]) between participants in the process of learning, it is important to investigate the role that contingency plays in the tutor's behavior with respect to synchrony. For instance, it might be the case that it is the infant, through her or his own feedback, who is actually designing the way the tutor is structuring the demonstrated action. The second issue regards the interdependence between the development of contingency and synchrony. The aim is to understand how synchronous behavior can be a basis for contingent behavior. Experiments on human–robot interaction, coupled with observations of parent-children tutoring situations, can shed light on these topics. In addition, the application of learning through interaction paradigms [117], [272] can help further robotic research to approach recognition or interaction capabilities (e.g., automatic speech recognition or dialog/contingency mechanisms), as it allows as it allows the analysis of more modalities (e.g., gaze, facial expressions for more socially related functions and hand movements/gestures for more task oriented functions), to develop new methodologies and to conduct evaluation cycles facilitating technical improvement.

C. Scaffolding of Behavioral, Linguistic, and Conceptual Competencies

In learning to use language to communicate and manipulate the world around them, human children benefit from a positive feedback loop involving individual learning (by interacting with their hands and bodies with objects around them), social

learning (via close interaction with parents and others), and gradual acquisition of linguistic competencies. This feedback cycle supports the scaffolding of increasingly complex skill learning and linguistic development giving the child ever greater mastery of its social and physical environment, as well as supporting the development of cognitive and conceptual capabilities that would seem impossible without language. To realize communication in robots a similar kind of feedback cycle supporting the scaffolding of behavioral, linguistic and conceptual competencies will be required. Such a realization will not only allow better understanding of possible mechanisms for such learning in humans, but also to achieve similar competencies in artificial agents and robots (even if they are not acquired by exactly the same routes).

Social interaction may also allow meaning to be grounded in early childhood language through shared referential inference in pragmatic interactions, whereby shared reference provides the necessary statistical bias to allow focused learning to take place. In order to create appropriate conditions for language learning in robots, it would therefore be necessary to expose the robot to similar physical and social contexts. This might be achieved via an interaction environment between a human and a robot where shared intentional-referencing and the associations between physical, visual, and speech modalities can be experienced by the robot. In fact, the bias of the learning context may require the human interaction partner to treat the robot as an intentional being, even though the robot may have no intentional capability [51]. The output of such studies, if combined to yield word or holophrase structures grounded in the robot's own actions and modalities, e.g., as in [205], would provide scaffolding for further protogrammatical usage-based learning. This requires interaction with the physical and social environment involving human feedback to bootstrap developing linguistic competencies. These structures could then form the basis for further studies on language acquisition, including the emergence of negation (see below) and more complex grammar.

A possible direction [206] for achieving such competencies is to study mechanisms whereby robots or other synthetic agents are expected to exhibit the following:

- holophrase learning;
- segmentation of utterances down to word level;
- the grounding of words and lexicon usage frames in action and object learning via physical interactions;
- the bootstrapping of simple usage-based protogrammatical structure via human scaffolding and feedback.

D. Negation

The emergence of various forms of negation [74], [157] through the mechanisms of communicative social interaction is considered to have been an extremely important qualifier in the emergence of symbolic representation capabilities. Very early in the language development of children negative speech acts emerge, such as the rejective and holophrastic "No!", e.g., to refuse certain food or a particular activity. Other functions of negation in early child language include nonexistence, prohibition, denial, inability, failure, ignorance, expressing the violation of a norm, and inferential negation [46].

The mentioned examples show that the various functions of early negation are not necessarily related to each other and that the term encompasses a set of functions that is remarkably larger in scope than the well known negation of propositions in particular. Which function a particular case of negation has is obviously highly context-dependent in more than one sense. It depends on the linguistic context on one hand but also on the situational context. An artificial agent that is supposed to appropriate negative human-like speech acts therefore cannot derive the meaning of these utterances through a simple lexical analysis. It has to take into account the situation in which the dialogue takes place (joint attentional frame). Current models either choose the representation of objects [201] or actions [207], [208] as basic representational building blocks. Different functions of negation tend to operate on the other hand more on objects (nonexistence) or more on actions (rejection, prohibition), which suggests that the support for certain forms of negation may be rather weak in each of these existing models. Thus, for achieving the emergence of the full range of early negation, ways have to be found to bypass these difficulties.

Future studies should consider questions such as: 1) Which features must be supported by frameworks for grounded language learning and imitative learning to enable the representation and production of speech acts that involve negation? 2) To what degree and in which form must motivation in the robotic platform be modeled for this purpose, as the majority of early negative speech acts are acts of volition and not acts of description? 3) Can negation emerge as purely syntactical construction or is it necessary to modify the underlying grounding mechanism?

E. Open and Challenging Research Questions in Social Learning and Language

Insights of Wittgenstein [267] and Millikan [144], and more constructively Steels [223], [228], suggest that to understand signaling and linguistic behavior, one needs to take into account usage in its pragmatic embodied social context. The learning of communicative signaling and linguistic systems (at the ontogenetic, diachronic, and evolutionary levels) are moreover shaped, not only by details of perception and embodiment, e.g., Cangelosi and Parisi [34], but also by details of transmission, sources of error and variability, as well as feedback and repair mechanisms, e.g., [217], [223], [271].

The overall approach is to understand constructively what mechanisms could be responsible for the ontogeny of linguistic competencies. That is, for such a constructive theory of language to be successful it is necessary to build an instantiation that exhibits the phenomenon to be explained, and, moreover, different constructive mechanisms could be assessed against each other by comparing what they actually generate. Preferably these constructivist evaluation test-beds must involve learning in embodied social interactions with humans and physical interactions with rest of the robot's environment.

Open and challenging research questions in this area include the following.

- To what extent can the methods be scaled for human-like acquisition of linguistic abilities?

- What "cognitive" capabilities are necessary for recruitment in the development of human-like linguistic competencies?
- Is it necessary to build in universal mechanisms for categorization and generalization, propositional logic, predication, compositional syntax, etc?
- Can these emerge from more elementary processes, such as Hebbian learning, "chunking," sequential processing and locality principles or more general cognitive capacities such as perspective taking; action hierarchies; expectation, prospection, and refusal?
- How can different types of linguistic negation be acquired by a robot or synthetic agent?
- To what extent are these mechanisms for the development of linguistic abilities universal, i.e., applicable for any given target natural language?
- What are appropriate semiotic frameworks for pragmatic acquisition of language usage (e.g., fluid construction grammar in Steels and Wellens, [224], [225], embodied construction grammar in Bergen and Chang, [19], or dynamic syntax in Kempson *et al.* [115])?
- To what extent are purported explanations consistent not only with individual ontogeny of linguistic capabilities but also with diachronic (transmission) and evolutionary (philogenetic) considerations?

VI. KEY CHALLENGE 4: PUTTING ACTION AND LANGUAGE TOGETHER AGAIN

The three sections above have considered, in part independently, the key research issues on action learning, lexicon acquisition and social interactions. However, as discussed in the introduction, and as supported by neuroscientific and psychological evidence, cognitive development and general cognitive processing are based on the strict interaction and codependence between language and action. This section focuses on the research issues that specifically address the form of language/action interaction and the phenomena underpinning it. Initially, the focus is on research based on neurorobotic models for investigating the neural representations of action and language. We then consider cognitive robotics approaches to the psychological phenomena of language grounding in action. Finally, we consider the phylogenetic dimension of cognition evolution and how robotics models can help us investigating the contribution of action cognition in the origins of language.

A. Neural Representations of Action and Language Knowledge

Neuropsychological and neuroscientific literature on language processing in the brain is quite extensive and consistently demonstrates the close integration of action and language processing [182]. For example, various studies have analyzed the neural correlates of the processing of various word classes and the verb-noun dissociation in patients. In Cappa and Perani [39], a review of the neuroscience studies on the neural processing of verbs and nouns is presented. The authors found a general agreement on the fact that the left temporal neocortex plays a crucial role in lexical-semantic tasks related to the processing of nouns whereas the processing of words related to actions (verbs) involves additional regions of the left dorsolateral prefrontal cortex. For example, in the well-known neuropsychological study on verbs and noun processing, Damasio and Tranel [55] reported that most of the patients with selective disorders of noun retrieval had lesions in the left temporal lobe. Instead, verb impairment was associated with damage on the left prefrontal cortex. In a PET study, Martin and colleagues [138] compared color naming (nouns) and action naming (verbs). They observed a selective activation for color naming of the left fronto-parietal cortex, the middle temporal gyrus, and the cerebellum. Perani, Cappa *et al.* [172] also used PET for the processing of concrete and abstract verbs and nouns in Italian. Results indicated that left dorsolateral frontal and lateral temporal cortex were activated only by verbs. In the comparison of abstract and concrete words, only abstract word processing was associated with selective activation of the right temporal pole and amygdala and the bilateral inferior frontal cortex. Finally, in evoked potential studies it was reported that there is selective activation of the frontal lobes for action words [180]. This difference is related to the semantic content of words rather than to grammatical differences, since no difference was observed between action verbs and nouns with a strong action association (Pulvermuller, Mohr, and Schliechert, [183], [184]).

Brain simulation models, such as those of computational neuroscience, have rarely focused on complex linguistic behavior, except for a few studies (e.g., Just *et al.* [111]). This is due to the complexity of the various linguistic functions (speech processing, lexical and semantic knowledge, syntax) to be included in a model. However, brain simulation models have been commonly developed for a variety of behavioral and cognitive abilities, such as vision, memory, and motor control. More recently, in such models the method of synthetic brain imaging [7], [104] has permitted a more strict integration of experimental data and computational models and a direct comparison of performance in artificial and natural brains. In addition, cognitive models based on neuro-cognitive robots can be used to investigate the neural correlates of motor and linguistic behavior. In Cangelosi and Parisi [36], a computational model of action and language learning is proposed that specifically looks at action/language integration. This model if based on simulated robots (i.e., agents with 2-D robotic arm for manipulating objects) that are evolved for their ability to: a) manipulate objects such as a vertical and a horizontal bar: and b) to learn lexicons describing the respective agent's interaction with the objects. The agent's motor and linguistic behavior is controlled by an artificial neural network. We study the consequences in the network's internal functional organization of learning to process different classes of words. Agents are selected for reproduction according to their ability to manipulate objects and to understand nouns (objects' names) and verbs (manipulation tasks). Synthetic brain imaging techniques [7] are then used to examine the functional organization of the neural networks. Results show that nouns produce more integrated neural activity in the sensory processing hidden layer, while verbs produce more integrated synaptic activity in the layer where sensory information is integrated with proprioceptive input. Such findings are qualitatively compared with human brain imaging data [39] that indicate that nouns activate

more the posterior areas of the brain related to sensory and associative processing while verbs activate more the anterior motor areas.

These results indicate how neurorobotic models, directly constrained on known neuroscientific and psychological phenomena, can be used to directly address some of the open questions on the neural representations of action and language knowledge. In particular, future developmental robotics studies based on neurorobotics agents can be used in the computational modeling of issues such as: 1) qualitative and quantitative differences in the neural representations of action and language concepts; 2) amount of overlap/difference between motor representation patterns and linguistic neural activations; 3) graduality of motor representation components in various syntactic classes; and 4) developmental timescale and dynamics in the acquisition of motor and linguistic concepts.

B. Action Bases of Language Processing

Psycholinguistic data on action-compatibility effects (ACE) during language comprehension tasks [85] support an embodied theory of language that strictly relates the meaning of sentences to human action and motor affordances. Glenberg and Robertson [86] have proposed the indexical hypothesis to explain the detailed interaction of language and action knowledge. This suggests that sentences are understood by creating a simulation of the actions that underlie them. When reading a sentence, the first process is to index words and phrases to objects in the environment or to analogical perceptual symbols. The second process is deriving affordances from the object or perceptual symbol. Finally, the third process is to mesh the affordances into a coherent set of actions. The meshing process is guided by the syntax of the sentence being processed. This suggests a parallel between syntax and action. Syntax has the role of combining linguistic components into an acceptable sentence. Motor control has the role of combining movements to produce the desired action. Moreover, Glenberg (personal communication) suggests that syntax emerges from using linguistic elements to guide mechanisms of motor control to produce effective action or a simulation of it. Such a view is compatible with construction grammar hypothesis that suggests that linguistic knowledge consists of a collection of symbolic form-meaning pairs reflecting, amongst other things, action roles and properties.

Developmental robotics experiments can be used to specifically investigate language grounding and action-compatibility effects in syntax processing. Robots can initially be trained to acquire an action repertoire producing various motor affordance representations and constructs (e.g., give-object-to, receive-object-from, lift-object, etc.). In parallel the robots will learn the names of actions and objects name. Further testing of the robot responses to ACE-like situations, and systematic analyses of the robot's internal (e.g., neural patterns controlling the robot motor and linguistic behavior) can provide insights on the fine mechanisms linking microaffordance action representations with language.

C. Evolutionary Origins of Action and Language Compositionality

The relationship between language and action is particularly important when we consider the striking similarities and parallels that have been demonstrated to exist between the linguistic structure and the organization of action knowledge. As discussed in Section III, action knowledge can be organized into compositional and hierarchical components. Language has two core characteristics: compositionality and recursion. Compositionality refers to the fact that a series of basic linguistic components (i.e., word categories such as nouns, verbs, adjectives, etc.) can be combined together to construct meaningful sentences. Recursion refers to the fact that these words and sentences can be recursively combined to express new sentences and meanings. These mechanisms create a parallel between the structure of language and that of meaning (including sensorimotor representations). When considering such remarkable similarities between language and action, some fundamental questions arise: Why do language and action share such hierarchical and compositional structure and properties? Is there a univocal relationship between them (e.g., the structure of action influences that of language, or vice-versa), or do they affect each other in a reciprocal way? Do these two abilities share common evolutionary, and/or developmental, processes?

These scientific questions will be investigated through new robotic experiments based on the combination of evolutionary algorithms and ontogenetic/developmental learning algorithms. These experiments will be based on robotic simulations due to time constraints involved in evolutionary computation (i.e., parallel testing of many robots within one generation, to be repeated for hundred of selection/reproduction cycles). Experiment will directly address some of the language origins hypotheses on action/language interaction. For example, one study will consider Corballis [50] hypothesis that language evolved from the primates' ability to use and make tools and the corresponding cognitive representation that such a compositional behavior requires. Evolutionary simulations will first look at the evolution of tool use and object manipulation capabilities. Subsequently, agents will be allowed to communicate about their action and object repertoire. The analysis of evolutionary advantages in preevolving object manipulation capability will be considered. Another simulation will consider Greenfield's [95] study on sequential sorting behavior and its relationship to language and motor development (evolutionary and ontogenetic). Children use different dominant strategies in sequential tasks such as nesting cups, e.g., from an early "pot" strategy (move one cup at a time) to a later "subassembly" strategy (moved pairs or triples of stacked cups). Greenfield suggests that language and sorting task processes are built upon an initially common neurological foundation, which then divides into separate specialized areas as development progresses. Such a hypothesis will be studied in simulation on the manipulations of the topology of the neural network controlling the agents' linguistic and motor behavior. Simulations will provide further insights on the evolutionary relationship between action and language structure, as well as providing new methodologies for the combination of evolutionary and ontogenetic learning mechanisms in communicating cognitive systems.

TABLE I

Action learning	Developmental learning of simple actions (primitives) Capacity to categories and name objects, events and states Ability to detect objects, gaze, reach and clasp the hand around the object	Acquisition of hierarchical and compositional actions	Learning the association between syntactic constructions and composite actions via social learning	Social based acquisition of action generalization rules Ability to correlate action and language generalization capabilities	Acquisition of the ability to generalize over goals Ability to correlate recursive /composite actions with recursive linguistic expressions	Ability to learn rich action repertoires based on social/linguistic descriptions
Language learning	Grounded acquisition, decomposition and generalization of simple transitive holophrases in learning by demonstration tasks	Grounded acquisition, decomposition and generalization of the five basic argument structure constructions of English from holophrastic instances in learning by demonstration tasks	Grounded interactive language learning games in simple joint attention scenarios based on the implementation of elementary socio-cognitive/pragmatic capabilities	Learning from increasingly more complex/diversified linguistic input within progressively less restricted learner-tutor interactions	Progressively more human-like cooperative ostensive-inferential communication based on the implementation of more advanced socio-cognitive/pragmatic capabilities	Learning progressively more complex grammars from quantitatively naturalistic input
Social learning	Harnessing of elementary non-verbal social cues (gaze, turn-taking, mirroring etc) to enhance social learning for language and skill acquisition Modeling holophrase acquisition via intermodal learning (acoustic packaging)	Development of a tutor spotter for social learning scenarios Joint intentional framing and referential intent Acquisition of negation usage of various types (eg refusal, absence, prohibition, propositional denial)	Development of architectures capable of exploiting pragmatic skills such as sequential interactional organization (contingency, turn-taking) and use of prosody for grammatical learning Harnessing of Model/Rival (M/R) learning, motivational systems and predictive social interaction	Exploiting interactions of prosody, internal motivation, inter-subjectivity and pragmatics in language acquisition and dialogue Developing architectures based on intermodal learning and sensitivity to a tutor	Temporally extended understanding of the social motivations and intentions of other minds, context, and (auto)biographic and narrative (re)construction Development of first systems that are capable of social learning and sequential organization of interaction in specific scenarios	Development of systems that are capable of social learning and pragmatic organization of interaction in various scenarios
Cognitive integration	Integration of basic action and naming representations and emergence of shared representation roles for both actions and names	Simulation of Action-Language Compatibility effects Co-evolution of action and language skills for simple grounded lexicons	Computational neuroscience models of action and language integration	Use of general purpose grammatical constructions for the creation of new complex motor and perceptual concepts	Scalable lexicons of abstract concepts based on the developmental acquisition of a grounding kernel	Acquisition of open repertoires of compositional actions and lexicons sharing natural language properties

VII. A ROADMAP FOR FUTURE RESEARCH

The above research issues constitute some of the key challenges for research in developmental cognitive robotics, in particular, regarding ongoing and future work on linguistic communication between robots and human–robot interaction. Other core issues in developmental robotics regard additional linguistic/communicative capabilities, such as new developments in phonetic and articulatory systems, or new insights in concept acquisition and the influence of language on the process, as well as additional cognitive and behavioral abilities. These include research on motivation and emotions, on perception and action, on social interaction, and on higher-order cognitive skills such as decision making and planning.

In addition to research specifically addressing individual cognitive skills and their interaction, other core cognitive robotics research issues regard general cognitive capabilities. In particular, two main challenges regard the further development of learning techniques (e.g., development of new, scalable learning algorithms) and the design of brain-inspired techniques for robot control.

If we consider future advancements on developmental robotics and the parallel progresses in the various cognitive and behavioral capabilities, we can identify a potential sequence of milestones for what regards specifically research on action and language learning and integration (Table I). These milestones provide a possible set of goals and test-scenarios, thus acting as a research roadmap for future work on cognitive robotics. That it, we do not intend to propose a fully defined and rigid sequential list of milestones, especially as there will be overlap of cognitive capabilities development in the transition between milestones/stages. We rather want to suggest specific experimental test scenarios and target cognitive capabilities that should be studied in future developmental robotics research.

These experimental scenarios can also be used to evaluate the progress in the various milestones.

For practical reasons, milestones are grouped along a temporal scale from the next two, four, and six to eight months, to a more distant times scale of 10, 15, and 20 years' perspective. The descriptions of the closest (two to eight years) three milestones will be more extensive that those for the more distance milestones (10 years and over), as it is very difficult to foresee now the detailed development for longer term goals.

A. Milestone for Action Learning Research

This section gives an overview of the six milestones on action learning. We will describe in more details the first three milestones given current state of the art and related foreseeable advancements in action learning research. The remaining longer term milestones will be briefly introduced, as their detailed specification will depend much on actual achievements in the preceding two to eight years of research.

Action Learning Milestone I (Next Two Years): The first milestone, crucial to development, has to do with the acquisition of the simplest possible actions. Actions here are intended not as simple movements and, therefore, we are not considering a purely motor—read muscular—aspect, but rather a complete sensorimotor primitive. We see action (as opposed to movement or reflexes) as goal-directed movements, initiated by a motivated subject and exploiting prospective capabilities (predicting the future course of the movement)—see [256]. This difference is important because it shifts the focus of observation from the control of the muscles to the connection between a goal, a motive and predictive information (e.g., the context of action execution). Actions are in a sense defined by the "goal" not by how the goal is achieved—that is, grasping can happen with the left or right hand as well as with the mouth. This is why the capacity of categorizing, perceiving objects, events and states

parallels the development of action (primitives). Developmental psychology supports this view as in, e.g., [270] together with neurophysiology as summarized in [108]. It is also evident that in humans, these abilities are prelinguistic (e.g., reaching develops at around month three, early grasping and manipulation soon after—month four–five—, the hand is adjusted to the object's size at around month nine and they are finally integrated in a single smooth action at around month 13 of age). It is worth noting that in human infants, action develops from preexisting basic structuring—both of the motor system [58] and of the somatotopy of the sensory system [110], [185], [255]. This pre-structuring seems to emerge from very specific mechanisms already in operation in the fetus. Similarly, some basic knowledge about objects (e.g., that motion boundaries are representative of objects), about numbers (e.g., one versus two, quantities) and about others (the presence of other people) seems to be available to the newborn [220].

This step, fundamental to human development, seems to be also necessary in building a robot that develops. Here, our hypothetical milestone has to include: the ability to detect objects (though not necessarily their identity), to gaze (although not as smoothly as in adults), and to reach and clasp the hand around the object. These abilities are supported by an improvement in the ability to predict internal dynamics (self-generated forces), sitting (thus freeing the hands from their support function) and by an improvement in vision (binocular disparity develops by month three or so), smooth pursuit becomes fully operational and by an increased social interaction (correct hemisphere of gaze). On the computational side, achieving a similar milestone requires methods for learning that show certain "good properties" like incremental learning, bounded memory, and representation complexity, and that provide certain guarantees (formal) of convergence. Ideally, the combination of full online methods with the good properties of convergence of batch methods should be used, although typically online methods are evaluated by the number of mistakes (to be bound) rather than convergence which lacks of clear significance [18].

Action Learning Milestone II (Next Four Years): Our second milestone refers to the flexible acquisition of action patterns and their combination to achieve more complex goals. Evidence from neurophysiology shows that this is the case also in the brain—for example, in nonhuman primates the flexible use of actions with respect to external visual cues has been demonstrated [70], [71]. Mirror responses have been found in the parietal cortex that depend on the goal of the action (e.g., eat versus place) as a function of the presence of certain objects (e.g., a tray for placing instructs the monkey to execute a place). Some neurons in this area start responding before the hand action becomes unambiguous showing that the extra visual cue (the tray) determines their activation. In a sense, the other's intention is encoded in the presence of the specific context (exemplified by the tray). For developmental robots the possibility of exploiting external or self-generated forces together with the flexible reuse of motion primitives is one step forward towards the acquisition of a "grammar" of action (or a vocabulary of actions as described by [67]). Here many different methods have been proposed in robotics, in particular, to represent complex actions as subactions and to combine them smoothly. These range from

the use of multiple forward-inverse models as in the well-known MOSAIC method [98] and the more recent HAMMER [60] to trajectory decomposition as in Billard *et al.* [21] or in [43] using a formalism derived from catastrophe theory. The problem of exploiting self-generated forces has been addressed recently by Nori *et al.* [164] and requires the autonomous acquisition of dynamical models of the body. This skill also requires "developmental learning" methods that can operate in high-dimensional spaces as in, e.g., [210]. An important element in the definition of motor primitives, their combination, and generation of action is the detection of affordances. The term affordance was originally used by Gibson [80] to refer to "action possibilities" on a certain objects, with reference to the actor's capabilities. More recently, neural responses which can be made analogous to the perception of affordances have been found in the monkey [76] and computational approaches were formulated in robotics [141]. It is possible to build formal models of affordances and relate learning, detection and imitation. This approach has been pioneered in models of the mirror neurons [142] and extended recently to include various modalities including word-object associations as in [120]. Bayesian methods form a very natural formalization of affordance learning by taking into account the uncertainty of the physical interaction between effectors and objects as well as the multiple action possibilities provided by objects to complex manipulation (e.g., with multiple fingers).

Action Learning Milestone III (Next Six to Eight Years): The third milestone regards the processes when social (imitation) learning word to object association starts to develop. Simultaneously it is possible to imagine simple syntactic associations between actions and objects via the affordance mechanism discussed above. At this stage, around the onset of the first single world-single object associations, infants are perfect at reaching and getting possess of objects, in detouring around barriers and in separating the "line of sight" from the "line of reach" thus, effectively enabling interaction in complex scenarios [62]. While social behaviors can be already seen in newborns, at this stage (12 months), infants acquire the ability to use pointing for sharing attention or requesting an object. Requests can be more subtle as asking for the object name, or information about the object. Some studies show that pointing at 12 months predicts speech production rates at 24 months [30] and that the combination of pointing and a word which differs from the object signed precedes two-word sentences, the first grammatical construction [91].

Action Learning Milestone IV (Next 10 Years): This longer term milestones refers to: 1) the acquisition of action generalization rules through social learning; and 2) the development of an ability to correlate action and language generalization capabilities though the sharing of representation and rules. For action generalization rules we refer here to the development of higher-order representation of action constructs that share common sensorimotor actuators and strategies.

Action Learning Milestone V (Next 15 Years): One component of this milestone refers to the acquisition of the ability to generalize over goals. Once the robot has developed goal-directed behavior for a larger set of independent goals, it can also acquire generalization capability for goals that share the same action and social roles. This milestone also focuses on further

extension and enhancement of the shared action/language integration system. For example, research should focus on the development of higher-order cognitive abilities to correlate recursive and composite actions with recursive syntactic construct.

Action Learning Milestone VI (20+ Years): This milestone regards further development of an open-ended capability to learn rich action repertoires based on complex social and linguistic descriptions, as also detailed in the Milestones VI of the language and social learning components.

B. Milestone for Language Learning Research

The language learning milestones follow an incremental nature dependent on the increase of the complexity of the learning architecture, scenario, and task.

Language Learning Milestone I (Next Two Years): This milestone documents the general feasibility of adopting a grounded neural network approach to learning an elementary repertoire of lexical items and productive basic sentence types (argument structure constructions) and provides a precise empirical characterization of the initial learning target, i.e., children's actual experience with the most basic English sentence types and their most common realizations in the input. In addition, work in this period lays the computational foundations for embodied robotic learning of the investigated patterns in restricted learning by demonstration tasks. Specifically, new research should demonstrate the acquisition of abstract grammatical constructions, proceeding from the acquisition of holistic utterance-scene pairs over the segmentation of recurrent constitutive elements of the acquired holophrases to their compositional recombination (i.e., generalization).

Language Learning Milestone II (Next Four Years): The milestone scales the lexicon up to multiple grammatical constructions that are acquired in parallel, ultimately embracing all five of the basic sentence type/argument structure constructions of English and the event types that are associated with their prototypical uses.

Language Learning Milestone III (Next Six to Eight Years): This introduces implementations of the most elementary sociocognitive/pragmatic capabilities that are required for simple linguistic interactions (e.g., joint attention, perspective taking, turn taking). With these capabilities in place, language learning experiments can shift from learning by demonstration to more naturalistic forms of language learning from social interaction (albeit initially confined to fairly rigidly restricted language games proceeding by fixed protocols).

Language Learning Milestone IV (Next 10 Years): This milestone marks a progressive diversification of the linguistic resources employed, as well as a more naturalistic approximation of their actual quantitative proportions in children's linguistic input, extending current learning architectures progressively to combine grounded learning with large scale distributional learning. Using corpora of child-directed speech as an empirical yardstick, more and more words and constructions are fed into the still restricted/non-spontaneous tutor-learner interaction according to distributional patterns extracted from naturally occurring child-directed speech.

Language Learning Milestone V (Next 15 Years): This relates to advanced skills of social cognition that must eventually be

incorporated into robotic systems at some point or other (however simplified) if serious progress towards human-like communicative capabilities is to be made: these higher level prerequisites for ostensive-inferential communication include such complex and contextually contingent capabilities as action recognition, goal inference, belief ascription, and everything else that is commonly subsumed under the notion of "shared intentionality" [249]. In general, the more aspects of these distinctly human traits can be adapted and rebuilt in artificial systems, the more open-ended the learner's capacity for flexible intelligent interaction during language learning tasks and communication experiments will be.

Language Learning Milestone VI (20+ Years): Finally, to the extent that all of the above has been integrated more or less successfully into a running system, milestone VI marks the stepwise addition of further grammatical and distributional complexity in order to further approximate the real-life challenge facing child language learners. Among other things, this additional complexity may relate to such dimensions as the relation between speech act participants and the proposition expressed (with the grammatical correlate sentence mood), the relation between speech act time and event time (grammatical reflex: tense) or the conceptualization of event structure and event sequencing (grammar: aspect). Likewise, the input used for pertinent learning experiments should increasingly resemble the quantitative properties of naturally occurring child-directed speech. In this, milestone VI marks incremental increases both in the grammatical and in the quantitative complexity of learners' linguistic input, thus paving the way to progressively open-ended interactional scenarios for grounded language learning experiments.

C. Milestone for Social Learning Research

Social Learning Milestone I (Next Two Years): The first target in social research involves studying and implementing nonverbal social cues for language and skill learning. The second target is modeling holophrase acquisition via intermodal learning; this entails sensitivity to aspects of acoustic packaging (cf. Section IV-C). The first target attempts to exploit biased learning via a form of rudimentary intentional reference. This can be achieved via joint attention between robot and human whereby the robot responds to gaze direction, mirroring and turn-taking in the interaction with the human interaction partner. The nonverbal clues direct robot attention to the actions or objects. Language acquisition proceeds by associating the robot's focus of attention (including its full sensorimotor feedback) with salient aspects of the human's speech modality.

The second challenge regards the modeling of holophrase acquisition via intermodal learning. This particularly refers to the implementation of the acoustic packaging that automatically permits the division of a sequence of events into units and thus there is synchrony between language and events.

Social Learning Milestone II (Next Four Years): The roadmap development in a four-year perspective within the social learning scenarios expects that an ability to detect and exploit tutoring interactions will be developed in humanoid robots. This would be achieved by extending and enhancing the developments in previous milestones. Scaffolded learning

of hierarchical behaviors in social interaction and the learning of grammar and vocabulary complement and enhance each other. Additionally further research on joint intentional framing and referential intent should be carried out together with the basic ideas for acquisition of negation usage of various types (e.g., refusal, absence, prohibition, propositional denial). Most of the latter require some modeling of motivation (volition and affect) on the part of the robot, as well as temporal scope encompassing memories and habits.

Tutoring plays an important role in understanding actions. Research would consider how tutoring could be used for learning, how complex actions could be structured, which kind of units could be observed, and how speech/sound signals (acoustic packaging) could be modeled. Studies would also be carried out to extend previous research in order to establish how to enhance rudimentary intentional reference to more sophisticated mechanisms for joint intentional framing and referential intent. This would take into account both interaction partners' gaze, speech, gesture, and motion clues. A further outcome of this milestone would be the acquisition of the meaningful usage of many forms of negation. Negation has been considered as a primarily grammatical phenomenon. However negation appears to be quite varied and emerges long before the production of grammatical utterances in young children. The part of the roadmap would lead to a better understanding of how negation fits into developmental learning and with the rest of language acquisition.

Social Learning Milestone III (Next Six to Eight Years): At this stage, we would expect that research will build on previous achievements to focus on two main areas of social learning and language. First, the development of architectures capable of exploiting pragmatic skills such as sequential interactional organization (contingency, turn-taking) and use of prosody for grammatical learning, and second, being able to harness model/rival (M/R) learning, motivational systems, and predictive models of social interaction. Prosodic bias occurring in speech directed at infants could be associated with gestural indications to not only highlight key parts of speech but also provide clues to the grammatical nature of language in the interaction.

A key issue in language research is also that of individuating participants and the acquisition of pronoun and anaphora usage and grammatical agreement based, e.g., on person and number and, in some languages, gender. For example, to understand that "I" means the speaker need not necessarily arise in pure two-way interaction (one interaction partner might use "I" to refer to themselves, but not to the other partner), however "I" can be obtained from three-way interaction. Furthermore, it has been shown from animal studies that a three-way interaction (introducing a rival who also acts as a model for functional use of utterances) accelerates (language) learning. Further investigations of the role of these interaction phenomena are necessary.

Social Learning Milestone IV (Next 10 Years): The 10-year goal would be to exploit interactions of prosody, internal motivation, intersubjectivity, and pragmatics in language acquisition and dialogue whilst developing architectures based on intermodal learning and sensitivity to a tutor.

Social Learning Milestone V (Next 15 Years): A longer term goal would be that of temporally extended understanding of

the social motivations and intentions of other minds, context, and (auto)biographic and narrative (re)construction. Thus rather than focusing and responding to events occurring in the immediate moment the robot language learner expands their scope to encompass a wider temporal horizon. This necessarily would require the development of mechanisms to cope with extended context including both the robot's own history and the ability to construct such events in relation to an interaction partner. We would envisage therefore the development of first systems that are capable of social learning and sequential organization of interaction in specific scenarios.

Social Learning Milestone VI (20+ Years): A very long term goal would be the development of systems that are capable of social learning and pragmatic organization of interaction related to grammar, language, and behavior in various open-ended scenarios. Clearly this would build of the achievements of earlier parts of the roadmap.

D. Milestone for Cognitive Integration Research

All previous milestones, though grouped for sake of clarity in the three research challenge areas of action, language and social learning, already include foreseen development that imply the integration of the tree cognitive capabilities. In the section below we will list additional future progress milestones not explicitly discussed in the previous section.

Cognitive Integration Milestone I (Next Two Years): This milestone explicitly refers to the development of robotics cognitive models able to integrate basic action and naming representations into emergence shared representation roles for both actions and names, implicitly integrating the capabilities discussed in the previous set of milestones. For example, any experiment of the learning of labels for individual objects and action categories should be implicitly linked, and integrated with, the experiment on the acquisition of new motor primitives and their application to object manipulation contexts. This integration assumes the sharing of internal representation and processes for both sensorimotor and linguistic knowledge. Such a progress in the acquisition of new action and language concepts is always developed in a social learning and imitation context.

Cognitive Integration Milestone II (Next Four Years): A further area of research achievable in a four-year perspective will be the simulation of embodiment phenomena in language learning robots such as the action-language compatibility effects (Glenberg and Kashark [85]; Tucker and Ellis 2004). Another milestone regards the development of evolutionary models demonstrating the coevolution of action and language skills for simple grounded lexicons and simple syntactic constructs (e.g., agent-verb-patient, agent-verb-preposition).

Cognitive Integration Milestone III (Next Six to Eight Years): Expected ongoing progress on the development of large-scale computational neuroscience models could lead to the application of these brain models to robotics action and language integration systems. This would for example build up on previous milestone reproducing behavioral action–language compatibility effects to computational neuroscience models investigating fine neural mechanism explaining facilitation and inhibition effects in multiple object scenarios (Ellis *et al.* 2007).

Cognitive Integration Milestone IV (Next 10 Years): This longer-term milestone refers to the development of general-purpose grammatical constructions for the creation of new complex motor and perceptual concepts. As specified in the language milestone IV section, at this stage a progressive diversification of the linguistic resources and acquisition of large scale distributional learning should be developed. In this integrative, milestone the focus in on how more advanced sensorimotor knowledge systems and richer social factors can help this complexification of the linguistic system.

Cognitive Integration Milestone V (Next 15 Years): New developments consequent to the acquisition or large lexicons and syntactic capabilities will allow the testing in robotics models of challenging research issues in embodiment literature. For example, the sensorimotor grounding of abstract concepts is a challenge for embodiment theory of cognition [6], [11], (Kousta *et al.* 1999). Embodied theories should be able to explain the contribution of sensorimotor and affective knowledge can explain the acquisition of abstract concepts, such as happiness and beauty, or nonsemantic words such as the function words "to" and "and."

Cognitive Integration Milestone VI (20+ Years): This longer term milestone refers to robotics experiments that can demonstrate the acquisition of open repertoires of compositional actions and lexicons sharing natural language properties. This could include emergent syntactic properties such as morphology, tense, and case agreement.

VIII. CONCLUSION

Overall, our vision for cognitive robotics research on action and language integration within the social learning context proposes the combination of a developmental approach to embodied machine learning with usage-based models of natural language acquisition [246] and construction-based theories of grammar (Goldberg 1995, [89]; Langacker, [124]). In this, it subscribes to basic tenets of cognitive-linguistic theories of child language acquisition such as the assumption that language learning:

- does not require substantial innate grammatical and sensorimotor hardwiring;
- is grounded in recurrent patterns of embodied experience and situated social interaction;
- builds on a set of preacquired social cognitive capabilities that are required for cooperative ostensive-inferential communication in general;
- proceeds through tacit distributional analysis of a noisy, but also richly structured linguistic input.

In order to implement these assumptions in a concrete agenda that can serve as an experimental roadmap and testbed for pertinent developmental research, we proposed that three key scientific challenges must be met.

- The development of scalable language processing and learning architectures that can (in principle) handle the full combinatorial complexity of natural language.
- The development of suitable implementations of basic social cognitive prerequisites for language acquisition

as identified by experimental research in developmental psychology.

- The development of empirically substantiated characterizations of the actual learning target and its stepwise appropriation by the learner as determined by empirical research on child language acquisition.

Consistently with the above developmental principles, in this paper we have identified a series of core research challenges in the different areas of action, language, and social learning, as well as challenges regarding their integration leading to the bootstrapping of further cognitive and linguistic capabilities. These principles have been translated in a practical roadmap based on a series of research milestones within a 20-year perspective. These milestones provide a possible set of goals and test-scenarios, thus acting as a research roadmap for future work on cognitive robotics. Although we do not propose these milestones to be a rigid set of fully defined and fully sequential research goals, they can however provide operational definitions of research objectives for the next two decades of research. This milestone list, together with other proposals on language development stages (see for example Steels, [226], grammaticalization stages), can contribute to the evaluation of advances for future developmental cognitive robotics research (e.g., Cangelosi *et al.*, [32]).

Angelo Cangelosi received the M.Sc. degree in experimental psychology from the University of Rome, Rome, Italy, in 1991, and received the Ph.D. degree in psychology and cognitive modeling from the University of Genoa, Genoa, Italy, in 1997, while also working as a visiting scholar at the National Research Council, Rome, the University of California San Diego, CA, and the University of Southampton, U.K.

He is currently a Professor of Artificial Intelligence and Cognition at the University of Plymouth, U.K., where he leads the Centre for Robotics and Neural Systems. He has produced more than 140 scientific publications, and has been awarded numerous research grants from the United Kingdom and international funding agencies for a total of over 10 million Euros. The books he has edited include *Simulating the Evolution of Language* (2002, Springer, coedited with D. Parisi) and *Emergence of Communication and Language* (2007, Springer; coedited with C. Lyon and C. L. Nehaniv). He is coordinator of the EU FP7 project "ITALK: Integration and Transfer of Action and Language Knowledge in Robot," a multipartner research project on action and language learning on the humanoid robot iCub. He also coordinates the "RobotDoC" Marie Curie doctoral network in developmental robotics, and the U.K. Cognitive Systems Foresight project "VALUE," cofunded by EPSRC, ESRC, and BBSRC.

Dr. Cangelosi is Co-Editor-in-Chief of the *Interaction Studies Journal* and serves on the editorial board of the *Journal of Neurolinguistics*, *Connection Science*, and *Frontiers in Neurorobotics*. He has chaired various international conferences, including the 6th International Conference on the Evolution of Language (Rome, Italy, 2006) and the 9th Neural Computation and Psychology Workshop (Plymouth, U.K., 2004). He has been invited/keynote speaker at numerous conferences and workshops.

Giorgio Metta received the M.Sc. degree (Honors) in 1994, and the Ph.D. degree in 2000, both in electronic engineering, from the University of Genoa, Genoa, Italy.

From 2001 to 2002, he was a Postdoctoral Associate with the Artificial Intelligence Laboratory, Massachusetts Institute of Technology, Cambridge, where he worked on various humanoid robotic platforms. He has been an Assistant Professor with the Dipartimento di Informatica Sistemistica e Telematica, University of Genoa, since 2005, where he has been teaching courses on anthropomorphic robotics and intelligent systems. Since 2006, he has also been a Senior Scientist with the Robotics, Brain, and Cognitive Sciences Department, Italian Institute of Technology, Genoa, Italy. His current research interests include biologically motivated humanoid robotics and, in particular, the development of artificial systems that show some of the abilities of natural systems. His research has been developed in collaboration with leading European and international scientists from different disciplines like neuroscience, psychology, and robotics. He is the author of more than 100 publications. He has also been engaged as a Principal Investigator and Research Scientist in several international and national funded projects. He has been reviewer of international journals and the journals of European Commission. He is also one of the leaders of the ROBOTCUB project, which resulted in the design and production of the humanoid robot iCub.

Gerhard Sagerer received the diploma and Ph.D. degrees in computer science from the University of Erlangen-Nürnberg, Erlangen, Germany, in 1980 and 1985, respectively. In 1990, he received the Habilitation degree in computer science from the Technical Faculty of the same university.

From 1980 to 1990, he was with the research group for pattern recognition at the Institut für Informatik, Mustererkennung, University of Erlangen-Nürnberg, Erlangen, Germany. Since 1990, he has been a Professor of Computer Science at the University of Bielefeld, Bielefeld, Germany, and Head of the Research Group for Applied Computer Science (Angewandte Informatik). During 1991–1993, he was a member of the Academic Senate of the University of Bielefeld. During 1993–1995 and again in 1997–2001, he was Dean of the Faculty of Technology of the university, and in 1995, he was chairman of the annual conference of the German Society for Pattern Recognition. He was Vice-Rector of the university from 2001 to 2007. Since 2007, he has been the Director of the Research Institute for Robotics and Cognition (CoR-Lab). From 2007–2009, he was Vice-Coordinator of the Centre of Excellence Cognitive Interaction Technology (CITEC). Since 2009, he has been Rektor of Bielefeld University. His fields of research are image and speech understanding including artificial intelligence techniques and the application of pattern understanding methods to natural science domains. He is author, coauthor, or editor of several books and technical articles.

Dr. Sagerer is member of the German Computer Society (GI) and the European Society for Signal Processing (EURASIP).

Stefano Nolfi received the B.A. and M.A. degrees in literature and philosophy from the University "La Sapienza," Rome, Italy, in 1987.

He is currently the Director of Research at the Institute of Cognitive Sciences and Technologies of the Italian National Research Council (CNR), Rome, Italy, where he leads the Laboratory of Autonomous Robotics and Artificial Life. He has been a fellow of the University of California, San Diego, SONY Computer Science Laboratory, Tokyo, Japan, the Institute for Advanced Studies of Berlin, Germany, and the University of New South Wales, Canberra, Australia. He has authored and coauthored more than 130 peer-reviewed scientific publications including *Evolutionary Robotics: The Biology, Intelligence, and Technology of Self-Organizing Machines* (Cambridge, MA: MIT Press/Bradford Books). He has been awarded numerous research grants from Italian and international funding agencies including the European Project on Embodied and Communicating Agents (ECAgents) that he coordinated. He is one of the inventors of the evolutionary robotic method for the synthesis of autonomous robots. His research interests include embodied cognition, language evolution and language development, adaptive behavior, and swarm intelligence.

Chrystopher Nehaniv received the B.Sc. degree from the University of Michigan, Ann Arbor, in 1987, and the Ph.D. degree in mathematics from the University of California, Berkeley, in 1992.

He is currently a Research Professor of Mathematical Evolutionary Computer Sciences at the University of Hertfordshire, Hatfield, U.K., where he founded the Adaptive Systems Research Group together with Kerstin Dautenhahn in 2000. His main interests include interactive systems, complex adaptive systems, artificial life, evolvability, emergence of language, and communication in embodied robots interacting with humans, as well as, abstract algebra (theory of semigroups, groups, and sequential machines) and its applications, especially, algebraic biology.

Dr. Nehaniv is also an Associate Editor of the journals *BioSystems* and *Interaction Studies*.

Kerstin Fischer received the M.A. and Ph.D. degrees from Bielefeld University, Bielefeld, Germany, in 1993 and 1998, respectively.

She is currently an Associate Professor for English Language and Linguistics at the University of Southern Denmark, Sonderborg, Denmark. Her research focuses on the use of construction grammar and other core cognitive linguistic concepts for the description of spoken interaction, and on verbal human–computer and human–robot interaction on the other.

Dr. Fischer is coeditor of the *Journal of Pragmatics and Society* and of the book series, *Studies in Pragmatics* (Emerald). She has also produced a broad range of publications on how people talk to computers and robots

Jun Tani received the B.Sc. degree in mechanical engineering from Waseda University, Tokyo, Japan, dual M.Sc. degrees in electrical engineering and mechanical engineering from University of Michigan, Ann Arbor, MI, and the Dr. Eng. degree from Sophia University, Japan.

He started his research career at the Sony Computer Science Laboratory in 1990. He has been Team Leader for the Laboratory for Behavior and Dynamic Cognition, Brain Science Institute, RIKEN, Tokyo, since 2000. He was also appointed as a Visiting Associate Professor in University of Tokyo from 1997 to 2002. His research interests include neuroscience, psychology, phenomenology, complex adaptive systems, and robotics.

Tony Belpaeme received the B.Sc. and M.Sc. degrees in electrical engineering. He also received the M.Sc. and Ph.D. degrees in computer science from the Vrije Universiteit Brussel, Belgium, in 1996 and 2003, respectively.

He was Postdoctoral Researcher and Guest Professor at the Artificial Intelligence Lab at the Vrije Universiteit Brussel. Since 2005, he has been an Associate Professor (Reader) in Intelligent Systems at the Centre for Robotics and Neural Systems, University of Plymouth, Plymouth, U.K. He is coordinator of the EU FP7 project "ALIZ-E: Adaptive Strategies for Sustainable Long-Term Social Interaction," which studies long-term human–robot interaction and the EPSRC CONCEPT project, which studies the acquisition and transfer of conceptual knowledge in robots. He is co-PI for the EU FP7 ITALK project and the "RobotDoC" Marie Curie doctoral network in developmental robotics. His research interests include the influence of language on cognition, symbol grounding, and the cognitive aspects of human–robot interaction.

Giulio Sandini is the Director of Research at the Italian Institute of Technology, Genoa, Italy, and a Full Professor of Bioengineering at the University of Genoa, Genoa, Italy. He graduated in electronic engineering (Bioengineering) from the University of Genova. He has been Research Fellow and Assistant Professor at the Scuola Normale Superiore, Pisa, Italy, and Visiting Research Associate at the Department of Neurology of the Harvard Medical School, Boston, MA. Since 2006, he has been Director of Research at the Italian Institute of Technology, where he has established and is currently directing the department of Robotics, Brain, and Cognitive Sciences.

Francesco Nori was born in Padova, Italy, in 1976. He received the Dipl. Ing. (Honors) and Ph.D. degrees from the University of Padova in 2002 and 2005, respectively.

During 2005 and 2006, he was a Postdoctoral Researcher at the University of Genova, Genova, Italy, collaborating with Prof. Giulio Sandini and Prof. Giorgio Metta within the activities of the laboratory for integrated and advanced robotics (LiraLab). Currently, he is Team Leader at the Italian Institute of Technology, Genoa, Italy, and he is one of the principal developers of the iCub humanoid robot with specific focus on the hardware and low level control. His current research interests are in motor control and in the application of modular structures to the control of complex nonlinear systems. In the past, he has been an active researcher in the fields of computer vision, system identification, and nonlinear control.

Luciano Fadiga received the M.D. degree from the University of Bologna, Bologna, Italy, in 1989, and the Ph.D. degree in neuroscience from the University of Parma, Parma, Italy, in 1994.

He is currently a Professor of Physiology at the University of Ferrara, Ferrara, Italy, and Senior Scientist at the Italian Institute of Technology, Genova, Italy. He is one of the discoverers of mirror neurons in macaque monkeys and has also provided empirical evidence by TMS and neuroimaging for the existence of a mirror-neuron system in humans. He has further demonstrated that the motor system becomes active both during action observation and during speech listening and, more recently, he has shown that this motor activation subserves speech perception. Among his current works is the central role of Broca's area, which is constantly activated by action observation, in pragmatically understanding the actions of others.

Britta Wrede received the M.Sc. degree in computational linguistics and the Ph.D. degree in computer science from Bielefeld University, Bielefeld, Germany, in 1999 and 2002, respectively.

She is head of the Hybrid Society Group at the Research Institute for Cognition and Robotics (CoR-Lab) at Bielefeld University, Germany. After receiving the Ph.D. degree, she received a DAAD Postdoc fellowship in the speech group of the International Computer Science Institute (ICSI), Berkeley, CA. Her research interests concern the modeling and bootstrapping of human–robot interactions based on pattern recognition methods.

Katharina Rohlfing received the M.Sc. degree in linguistics, philosophy, and media studies from the University of Paderborn, Paderborn, Germany, in 1997. She received the Ph.D. degree in linguistics from the Bielefeld University, Bielefeld, Germany, in 2002.

Since May 2008, she has been head of the Emergentist Semantics Group within the Center of Excellence Cognitive Interaction Technology, at Bielefeld University, where she is interested in learning processes. Her postdocotoral work at the San Diego State University, the University of Chicago, and Northwestern University was supported by a fellowship within the Postdoc-Program of the German Academic Exchange Service (DAAD) and by the German Research Foundation (DFG). In 2006, she became a Dilthey-Fellow (funding initiative "Focus on the Humanities") and her current project on the "Symbiosis of Language and Actions" is supported by the Volkswagon Foundtation. In her research, she is investigating the interface between cognitive development and early stages of language acquisition.

Elio Tuci received the M.Sc. degree in experimental psychology from ''La Sapienza'' University of Rome, Rome, Italy, in 1996. He received the Ph.D. degree in computer science and artificial intelligence from the University of Sussex, Brighton, U.K., in 2004.

He currently is a researcher at the Institute for Cognitive Science and Technology of the National Research Council, Rome, Italy. His research interests concern the development of real and simulated embodied agents to look at scientific questions related to the mechanisms and/or the evolutionary origins of individual and social behavior, and communication.

Kerstin Dautenhahn received the Ph.D. degree from the Biological Cybernetics Department of the University of Bielefeld, Bielefeld, Germany, in 1993.

She is a Professor in the School of Computer Science at University of Hertfordshire, Hatfield, U.K., where she coordinates the Adaptive Systems Research Group. She has pioneered research in social robotics, human–robot interaction, assistive technology, and published more than 200 research articles. She has edited several books and frequently gives invited keynote lectures at international meetings. She organizes international conferences and has been Principal Investigator of her research team in several European projects.

Prof. Dautenhahn is Editor-in-Chief of the *Journal of Interaction Studies: Social Behavior and Communication in Biological and Artificial Systems*, as well as Associate Editor of several other international journals.

Joe Saunders received the M.Sc. and Ph.D. degrees in computer science from the University of Hertfordshire, Hatfield, U.K., in 2003 and 2007, respectively.

He has published research articles on robot learning, imitation, and human–robot interaction, and is currently involved in several European robotics projects. Prior to 2003, he directed large software development projects for a number of international investment banks. His research interests include social robotics, language, and imitation in artificial systems.

Arne Zeschel received the Staatsexamen degree from the University of Hanover, Hanover, Germany, in 2001, and the Ph.D. degree in english linguistics from the University of Bremen, Bremen, Germany, in 2007.

He is currently working as a Postdoctoral Researcher on construction-based approaches to child language acquisition at the University of Southern Denmark, Sonderborg, Denmark. His main research interests are cognitive linguistics, corpus linguistics, and usage-based linguistic model building.
