Abstract—Network systems often rely on distributed algorithms to achieve a global computation goal with iterative local information exchanges between neighbor nodes. To preserve data privacy, a node may add a random noise to its original data for information exchange at each iteration. Nevertheless, an eavesdropping node can estimate other’s original data based on the information it received. The estimation accuracy and data privacy can be measured in terms of $(\epsilon, \delta)$-data-privacy, defined as the probability of $\epsilon$-accurate estimate (the difference of an estimation and the original data is within $\epsilon$) is no larger than $\delta$ (the disclosure probability). How to optimize the estimation and analyze data privacy is a critical and open issue. In this paper, a theoretical framework is developed to investigate how to optimize the estimation of neighbor’s original data using the local information received, named optimal distributed estimation. Then, we study the disclosure probability under the optimal estimation for data privacy analysis. We further apply the developed framework to analyze the data privacy of the privacy-preserving average consensus algorithm and identify the optimal noises for the algorithm.

Index Terms—Distributed algorithm, noise adding mechanism, distributed estimation, data privacy, average consensus.

I. INTRODUCTION

W

ithout relying on a central controller, distributed algorithms are robust and scalable, so they have been widely adopted in network systems to achieve global computation goals (e.g., mean and variance of the distributed data) with iterative local information exchanges between neighbor nodes [1]–[3]. In many scenarios, e.g., social networks, the nodes’ original data may include users’ private or sensitive information, e.g., age, income, daily activities, and opinions. With the privacy concern, nodes in the network may not be willing to share their real data with others. To preserve data privacy, a typical method is adding random noises to the data to be released in each iteration. With the noise adding procedure, the goal of privacy-preserving distributed algorithms is to ensure data privacy while achieving the global computation goal [4]–[6].

Average consensus, an efficient distributed computing and control algorithm, has been heavily investigated and widely applied, e.g., in distributed estimation and optimization [7]–[9], sensor data fusion [10], distributed energy management and scheduling [11], [12], and time synchronization in sensor networks [13]–[15]. The final goal of averaging is critical in these applications, e.g., the effective data fusion requires an accurate average consensus. Recently, how to ensure accurate average consensus while preserving privacy has attracted attention [16]–[20]. The main solution is to add variance decaying and zero-sum random noises during each iteration of the consensus process.

In the literature, differential privacy has been defined and applied for quantifying to what extent individual privacy in a statistical database is preserved [21]. It aims to provide means to maximize the accuracy of queries from statistical databases while maintaining indistinguishability of its transcripts. To guarantee the differential privacy, a commonly used solution is to add Laplacian noise [22], [23]. More privacy definitions (e.g., identifiability, differential privacy) and the relationships among them have been discussed in [28].

Different from the database query problems, for many distributed computing algorithms such as consensus, the key privacy concern is to ensure that other nodes cannot accurately estimate the original data, rather than the indistinguishability. No matter what type of noise distribution is used, there is a chance that an estimated value of the original data is close to the real data, and such a probability cannot be directly measured by differential privacy. To quantify the estimation accuracy and data privacy, we first define $\epsilon$-accurate estimate, i.e., the difference of the estimated value and the original data is no larger than $\epsilon$. Then, $(\epsilon, \delta)$-data-privacy is defined as that the probability of $\epsilon$-accurate estimate by an eavesdropper is no larger than $\delta$. Using the $(\epsilon, \delta)$-data-privacy definition, in this paper, we develop a theoretical framework to investigate how to optimize the estimation of neighbor’s original data using the local information received, named optimal distributed estimation. Then, we study the disclosure probability under the optimal estimation for data privacy analysis. The main contributions of this work are summarized as follows.

1) To the best of our knowledge, this is the first work to mathematically formulate and solve the optimal distributed estimation problem and data privacy problem.
for the distributed algorithm with a general noise adding mechanism. The optimal distributed estimation is defined as the estimation that can achieve the highest disclosure probability, $\delta$, of $\epsilon$-accurate estimate, given the available information set.

2) A theoretical framework is developed to analyze the optimal distributed estimation and data privacy by considering the distributed algorithm with a noise adding procedure, where the closed-form solutions of both the optimal distributed estimation and the privacy parameter are obtained. The obtained results show how the iteration process and the noise adding sequence affect the estimation accuracy and data privacy, which reveals the relationship among noise distribution, estimation and data privacy.

3) We apply the obtained theoretical framework to analyze the privacy of a general privacy-preserving average consensus algorithm (PACA), and quantify the $(\epsilon, \delta)$-data-privacy of PACA. We also identify the condition that the data privacy may be compromised. We further obtain the optimal noise distribution for PACA under which the disclosure probability of $\epsilon$-accurate estimate is minimized, i.e., the highest data privacy is achieved.

The rest of this paper is organized as follows. Section II provides preliminaries and formulates the problem. The optimal distributed estimation and the privacy analysis under different available information set are discussed in Sections III and IV, respectively. In Section V, we apply the framework to analyze the data privacy of PACA. Concluding remarks and further research issues are given in Section VI.

II. PRELIMINARIES PROBLEM FORMULATION

A network system is abstracted as an undirected and connected graph, denoted by $G = (V, E)$, where $V$ is the set of nodes and $E$ is the set of edges. An edge $(i, j) \in E$ exists if and only if (iff) node $i$ can exchange information with node $j$. Let $N_i = \{j | (i, j) \in E\}$ be the neighbor set of node $i$ ($i \notin N_i$). Let $n = |V|$ be the total number of nodes and $n \geq 3$. Each node $i$ in the network has an initial scalar state $x_i(0) \in \mathcal{R}$, which can be any type of data, e.g., the sensed or measured data of the node. Let $x(0) = [x_1(0), \ldots, x_n(0)]^T \in \mathcal{R}^n$ be the initial state vector.

A. Privacy-Preserving Distributed Algorithm

The goal of a distributed algorithm is to obtain the statistics of all nodes’ initial states (e.g., the average, maximum, or minimum value, variance, etc.) in a distributed manner. Nodes in the network use the local information exchange to achieve the goal, and thus each node will communicate with its neighbor nodes periodically for data exchange and state update. With the privacy concerns, each node is not willing to release its real initial state to its neighbor nodes. A widely used approach for the privacy preservation is adding random noise at each iteration for local data exchange.

Define $x_i^+(k)$ the data being sent out by node $i$ in iteration $k$, given by

$$x_i^+(k) = x_i(k) + \theta_i(k), \quad (1)$$

where $\theta_i(k) \in \Theta_i$ is a random variable and the noises added in iteration $k_1$ and $k_2$, $\theta_i(k_1)$ and $\theta_i(k_2)$ may be dependent of each other for $k_1 \neq k_2$. When node $i$ receives the information from its neighbor nodes, it updates its state using the following function,

$$x_i(k + 1) = h_i(x_i^+(k), x_j^+(k) : j \in N_i), \quad (2)$$

where the state-transition function, $h_i : \mathcal{R} \times \mathcal{R} \times \cdots \times \mathcal{R} \rightarrow \mathcal{R}$, depends on $x_i^+(k)$ and $x_j^+(k)$ for $j \in N_i$. The above equation defines a distributed iteration algorithm with privacy preserving since only the neighbor nodes’ information is used for state update in each iteration and the data exchanged has been mixed with random noises to preserve privacy. Hence, (2) is named as a privacy-preserving distributed algorithm. Since the initial state is most important for each node in the sense of privacy, in this paper, we focus on the estimation and privacy analysis of nodes’ initial states.

B. Important Notations and Definitions

Define the noise input and state/information output sequences of node $i$ in the privacy-preserving distributed algorithm until iteration $k$ by

$$I^n_i(k) = \{\theta_i(0), \ldots, \theta_i(k)\}, \quad (3)$$

and

$$I^\text{out}_i(k) = \{x_i^+(0), \ldots, x_i^+(k)\}, \quad (4)$$

respectively. Note that for any neighbor node $j \in N_i$, it cannot only receive the information output $I^\text{out}_i(k)$ of node $i$, but also eavesdrop the information output of their common neighbor nodes, which means that there may be more information available for node $j$ to estimate $x_i(0)$ at iteration $k \geq 1$. Since node $j$ can have the information output of all the common neighbor nodes between node $i$ and itself, we define

$$I^j_j(k) = \{x_i^+(0), x_i^+(0), \ldots, x_i^+(k), x_j^+(k) | \ell \neq j \text{ or } \ell \in N_i \cap N_j\},$$

as the available information set/outputs for node $j$ to estimate $x_i(0)$ of node $i$ at iteration $k$. Clearly, we have $I^\text{out}_i(k) = I^j_j(0)$ and $I^{\text{out}}_i(k) \subseteq I^j_j(k)$.

</table>
Let \( f_{\theta_j(k)}(z) \) be the probability density function (PDF) of random variable \( \theta_j(k) \). Let \( \mathcal{X}_i \subseteq \mathcal{R} \) be the set of the possible values of \( x_i(0) \). Clearly, if \( \mathcal{X}_i = \mathcal{R} \), it means that \( x_i(0) \) can be any value in \( \mathcal{R} \). Given any function \( f(y) \), we define the function \( f(y, \epsilon) \) as
\[
f(y, \epsilon) = f(y + \epsilon) - f(y - \epsilon),
\]
and let
\[
\Omega_f^\epsilon = \{y | f(y, \epsilon) = 0\}
\]
be the zero-point set of \( f(y, \epsilon) = 0 \). Let \( \{\omega\}_n \) be the boundary point set of a given set \( \{\omega\} \), e.g., \( \{0, 1\}_0 = \{0, 1\} \).

Note that each node can estimate its neighbor nodes’ initial states based on all the information it knows, i.e., the available information set of the node. For example, based on \( I_i^0(0) = x_i^0(0) \), node \( j \) can take the probability over the space of noise \( \theta_j(0) \) (where the space is denoted by \( \Theta_j(0) \)) to estimate the values of the added noises, and then infer the initial state of node \( i \) using the difference between \( x_i^0(0) \) and the real initial state \( x_i(0) \), i.e., \( \hat{x}_i(0) = x_i^0(0) - \hat{\theta}_i(0) \). Hence, we give two definitions for the estimation as follows.

**Definition 1:** Let \( \hat{x}_i \) be an estimate of variable \( x_i \). If \( |x_i - \hat{x}_i| \leq \epsilon \), where \( \epsilon \geq 0 \) is a small constant, then we say \( \hat{x}_i \) is an \( \epsilon \)-accurate estimate.

Note that \( I_i^\text{out}(k) \) is the information output sequence of node \( i \), which is related to \( x_i(0) \) directly, and this should be considered in the estimation. Since only the local information is available, we define the optimal distributed estimation of \( x_i(0) \) as follows.

**Definition 2:** Let \( I_i^\text{out}(k) \) be the possible output given the condition that \( x_i(0) = \nu \) at iteration \( k \). Considering \( \epsilon \)-accurate estimate, under \( I_j^0(k) \),
\[
\hat{x}_i^*(k) = \arg \max_{\hat{x}_i \in \mathcal{X}_i} \Pr \{ I_i^\text{out}(k) = I_i^\text{out}(k) | \forall |\nu - \hat{x}_i| \leq \epsilon \},
\]
is named the optimal distributed estimation of \( x_i(0) \) at iteration \( k \). Then, \( \hat{x}_i^* = \lim_{k \to \infty} \hat{x}_i^*(k) \) is named the optimal distributed estimation of \( x_i(0) \).

In order to quantify the degree of the privacy protection of the privacy-preserving distributed algorithm and construct a relationship between estimation accuracy and privacy, we introduce the following \((\epsilon, \delta)\)-data-privacy definition.

**Definition 3:** A distributed randomized algorithm is \((\epsilon, \delta)\)-data-private, if
\[
\delta = \Pr(|\hat{x}_i^* - x_i(0)| \leq \epsilon),
\]
where \( \delta \) is the disclosure probability that the initial state \( x_i(0) \) can be successfully estimated by others using the optimal distributed estimation in a given interval \([x_i(0) - \epsilon, x_i(0) + \epsilon]\).

In the above definition, \( \hat{x}_i^* \) depends on the output sequences, \( I_i^\text{out}(k) \), which are the functions of random noise inputs \( I_j^0(k) \) and its neighbors’ output \( I_j^\text{out}(k), j \in \mathcal{N}_i \). All the possible outputs of \( I_i^\text{out}(k) \) under a privacy-preserving distributed algorithm should be considered to calculate \( \delta \), and thus \( \hat{x}_i^* \) is a random variable in (7). There are two important parameters in the privacy definition, \( \epsilon \) and \( \delta \), where \( \epsilon \) denotes the estimation accuracy and \( \delta \) is the disclosure probability (\( \delta \leq 1 \)) denoting the degree of the privacy protection. A smaller value of \( \epsilon \) corresponds to a higher accuracy, and a smaller value of \( \delta \) corresponds to a lower disclosure probability.

**C. Problem of Interests**

We have the following basic assumptions, i) if there is no information of any variable \( y \) in estimation, then the domain of \( y \) is viewed as \( \mathcal{R} \), ii) unless specified, the full knowledge of the global topology information is unknown to each node, but each node can have partial knowledge of the topology, for example each node can know its local connecting nodes (e.g., the local topology information among each node and its neighbor nodes is known), iii) the initial states of nodes in the network are independent of each other, i.e., each node cannot make a good estimation of the other nodes’ state directly based on its own state or the estimation is of low accuracy.

In this paper, we aim to provide a theoretical framework of the optimal distributed estimation and data privacy analysis for the privacy-preserving distributed algorithm (2). Specifically, we are interested in the following three issues: i) how to obtain the optimal distributed estimation and its closed-form expression considering the distributed algorithm as follows; ii) using the \((\epsilon, \delta)\)-data-privacy definition to analyze the privacy of the distributed algorithm (2), i.e., obtaining the closed-form expression of the disclosure probability \( \delta \) and its properties; and iii) using the obtained theoretical results to analyze the privacy of the general privacy-preserving average consensus algorithm, and finding the optimal noise adding process to the algorithm, i.e., solving the following optimization problem,
\[
\min_{\delta} \lim_{k \to \infty} I_i^\text{out}(k) \quad \text{s.t.} \quad \lim_{k \to \infty} x_i(k) = \bar{x},
\]
where \( \bar{x} = \frac{\sum_{i=1}^{n} x_i(0)}{n} \) is the statistic goal, aiming at minimizing the disclosure probability while obtaining the average value of all initial states.

To solve the above issues, in the following, we first consider the case that only the one-step information output \( I_i^\text{out}(0) = I_j^0(0) \), which depends on the initial state \( x_i(0) \) and the one-step noise \( \theta_i(0) \), is available, and obtain the optimal distributed estimation and privacy properties. This case is suitable for the general one-step random mechanism (e.g., [24, 27]), and the theoretical results provide the foundations of the following analysis. Then, we consider the optimal distributed estimation under the information set \( I_j^1(1) \), which reveals how the iteration process affects the estimation and helps understand the optimal distributed estimation given the information set \( I_j^1(k) \) \((k \geq 1)\). Based on the observations, we extend the results to the general case that \( I_j^1(k) \) \((\forall k \geq 0)\) is available for the estimation. Lastly, we apply the obtained results to the general PACA algorithm for privacy analysis, and discuss the optimal noises for preserving data privacy.

### III. OPTIMAL DISTRIBUTED ESTIMATION AND PRIVACY ANALYSIS UNDER \( I_j^1(0) \)

In this section, the optimal distributed estimation of \( x_i(0) \) using \( I_j^1(0) \) only is investigated, and the disclosure probability \( \delta \) under the optimal estimation is derived.
A. Optimal Distributed Estimation Under $I'_{j}(0)$

Let $\hat{\theta}(0)$ be the estimate of $\theta(0)$ under $I'_{j}(0)$. The optimal distributed estimation of $x_{i}(0)$ under $I'_{j}(0)$ and its closed-form expression are given in the following theorem.

Theorem 4: Considering the distributed algorithm (2), under $I'_{j}(0)$, the optimal distributed estimation of $x_{i}(0)$ satisfies

$$\hat{x}_{i}^{*}(0) = x_{i}^{+}(0) - e_{\hat{\theta}(0)}(x_{i}^{+}(0)),$$

where

$$e_{\hat{\theta}(0)}(x_{i}^{+}(0)) = \arg\max_{y \in [x_{i}^{+}(0) - X_{i}]} \int_{y-\epsilon}^{y+\epsilon} f_{\hat{\theta}(0)}(z)dz;$$

(10)

Specifically, if $X_{i} = R$, then

$$\hat{x}_{i}^{*}(0) = x_{i}^{+}(0) - e_{\hat{\theta}(0)},$$

(11)

where

$$e_{\hat{\theta}(0)} = \arg\max_{y \in R} \int_{y-\epsilon}^{y+\epsilon} f_{\hat{\theta}(0)}(z)dz;$$

(12)

which is independent of $x_{i}(0)$.

Proof: Given $I'_{out}(0)$ and an estimate $\hat{x}_{i}(0)$, we have

$$\Pr \{ I'_{out}(0) = I''_{out}(0) | \forall |y - \hat{x}_{i}(0)| \leq \epsilon \}$$

$$\Pr \{ y + \hat{\theta}(0) = x_{i}^{+}(0) | \forall |y - \hat{x}_{i}(0)| \leq \epsilon \}$$

$$= \int_{x_{i}^{+}(0) - \hat{x}_{i}(0) - \epsilon}^{x_{i}^{+}(0) - \hat{x}_{i}(0) + \epsilon} f_{\hat{\theta}(0)}(z)dz.$$

(13)

From Definition 2, it follows that

$$\hat{x}_{i}^{*}(0) = \arg\max_{\hat{x}_{i}(0) \in X_{i}} \Pr \{ I'_{out}(0) = I''_{out}(0) | \forall |y - \hat{x}_{i}(0)| \leq \epsilon \}$$

$$= \arg\max_{\hat{x}_{i}(0) \in X_{i}} \int_{x_{i}^{+}(0) - \hat{x}_{i}(0) - \epsilon}^{x_{i}^{+}(0) - \hat{x}_{i}(0) + \epsilon} f_{\hat{\theta}(0)}(z)dz$$

$$= \int_{x_{i}^{+}(0) - \epsilon}^{x_{i}^{+}(0) + \epsilon} f_{\hat{\theta}(0)}(z)dz,$$

(14)

which concludes that (9) holds.

If $X_{i} = R$, for any real number output of $x_{i}^{+}(0)$, we have

$$|x_{i}^{+}(0) - X_{i}| = |x_{i}^{+}(0) - R| = R.$$

In this case, we have

$$\arg\max_{y \in [x_{i}^{+}(0) - X_{i}]} \int_{y-\epsilon}^{y+\epsilon} f_{\hat{\theta}(0)}(z)dz$$

$$= \arg\max_{y \in R} \int_{y-\epsilon}^{y+\epsilon} f_{\hat{\theta}(0)}(z)dz.$$

(15)

Substituting (15) into (14) gives

$$\hat{x}_{i}^{*}(0) = x_{i}^{+}(0) - \arg\max_{y \in R} \int_{y-\epsilon}^{y+\epsilon} f_{\hat{\theta}(0)}(z)dz$$

$$= x_{i}^{+}(0) - e_{\hat{\theta}(0)},$$

i.e., (11) holds. Thus, we have completed the proof.

In (9), $e_{\hat{\theta}(0)}(x_{i}^{+}(0))$ can be viewed as the estimation of the noise $\hat{\theta}(0)$, i.e., $\hat{\theta}(0) = e_{\hat{\theta}(0)}(x_{i}^{+}(0))$. Thus, (9) can be written as

$$\hat{x}_{i}^{*}(0) = x_{i}^{+}(0) - \hat{\theta}(0),$$

where $\hat{\theta}(0)$ is the estimate of $\theta(0)$ under $I'_{j}(0)$.
Fig. 2. The optimal distributed estimation of $e_{\theta_0}(x_i^+(0))$ and the optimal estimation of $\theta_0(0)$ with MAP.

follows from (10) that $e_{\theta_0}(x_i^+(0))$ is either one of the extreme points of $\int_{y-\epsilon}^{y+\epsilon} f_{\theta_0}(z)dz$ (i.e., $e_{\theta_0}(x_i^+(0)) \in \Omega^2_{\theta_0(0)}$) or one of the boundary points of $\{x_i^+(0) - \mathcal{X}_i\}$ (i.e., $e_{\theta_0}(x_i^+(0)) \in \{x_i^+(0) - \mathcal{X}_i\}$), b. Let

$$\mathcal{X}_{X_i^+}(0) = \{x_i^+(0) - \mathcal{X}_i\} \cap \Omega^2_{\theta_0(0)} \cup \{x_i^+(0) - \mathcal{X}_i\},$$

we then have

$$e_{\theta_0}(x_i^+(0)) = \arg \max_{y \in \mathcal{X}_{X_i^+}(0)} \int_{y-\epsilon}^{y+\epsilon} f_{\theta_0}(z)dz. \quad (16)$$

Applying the above general approach to the example of Fig. 1, one can easily obtain that

$$\mathcal{X}_{X_i^+}(0) = \{x_i^+(0), x_i^+(0) + a\}$$

and $\mathcal{X}_{X_i^+}(0) = \{0\}$ for the two cases, respectively. Based on (16), we obtain the same optimal estimations for the two cases.

Remark 5: From the above discussion, it is observed that $e_{\theta_0}(x_i^+(0))$ is the point $y$ that $f_{\theta_0}(z)$ has the largest $\epsilon$-shaded area around point $y$, where $y \in \{x_i^+(0) - \mathcal{X}_i\}$. It should be pointed out that $e_{\theta_0}(x_i^+(0))$ is in $\{x_i^+(0) - \mathcal{X}_i\}$ and depends on $\epsilon$, and thus it may not be the point that has the maximum value of $f_{\theta_0}(z)$. However, if $\epsilon$ is sufficiently small and $f_{\theta_0}(z)$ is continuous, $f_{\theta_0}(z)$ typically has the largest $\epsilon$-shaded area at point $y$ when $f_{\theta_0}(y)$ has the maximum value for $y \in \{x_i^+(0) - \mathcal{X}_i\}$. Meanwhile, the above examples also show that the unbiased estimation also may not be the optimal distributed estimation of $x_i(0)$.

It should be pointed out that the proposed optimal estimation problem is different from the maximum a posteriori estimation (MAP) problem that has been heavily investigated. The reason is that MAP ignores the estimation accuracy of $[x_i - \hat{x}_i]$ and it does not depend on the accuracy parameter $\epsilon$, while the proposed estimation problem aims to maximize the probability of $\epsilon$-accurate estimation and the optimal estimation is a function of the accuracy parameter $\epsilon$. An example to illustrate the difference is given as follows. As shown in Fig. 2, we consider a bimodal distribution of $f_{\theta_0}(z)$, in which the highest mode is uncharacteristic of the majority of the distribution. Assume that a prior distribution $g_i$ over $x_i(0)$ exists and is uniform with a large possible value domain $[-M, M]$. Using MAP, one obtains

$$\hat{x}_i(0) = \arg \max_{x_i(0)} f_{\theta_0}(x_i(0)|x_i^+(0))$$

$$= \arg \max_{x_i(0)} f_{\theta_0}(x_i^+(0)|x_i(0))g_i(x_i(0))$$

$$= \arg \max_{x_i(0)} f_{\theta_0}(x_i^+(0)|x_i(0))$$

$$= x_i^+(0) - a. \quad (17)$$

Using the proposed optimal estimation (Theorem 4), we have $\hat{x}_i^*(0) = x_i^*(0)$ which is different from the estimation (17) obtained with MAP.

B. Privacy Analysis Under $I_i^I(0)$

In the above subsection, we have obtained the optimal distributed estimation when $I_{i^out}(0)$ is fixed. Note that

$$|\hat{x}_i^*(0) - x_i(0)| \leq \epsilon \Leftrightarrow |x_i^+(0) - x_i(0) - e_{\theta_0}(x_i^+(0))| \leq \epsilon \Leftrightarrow |\theta_i(0) - e_{\theta_0}(x_i^+(0))| \leq \epsilon \quad (18)$$

when $x_i^+(0)$ is fixed. To analyze the privacy of distributed algorithm (2) with the $(\epsilon, \delta)$-data-privacy definition, the main goal is to calculate the disclosure probability $\delta$, so that all the possible initial output $x_i^+(0)$ and its corresponding optimal distributed estimation should be considered. Considering the outputs which can make an $\epsilon$-accurate estimates of $x_i(0)$ to be obtained, we define all the corresponding noises by

$$S_i(0) = \{\theta_i(0) \mid |e_{\theta_0}(x_i^+(0)) - \theta_i(0)| \leq \epsilon\}. \quad (19)$$

For each $\theta_i(0) \in S_i(0)$, we have $x_i^+(0) = x_i(0) + \theta_i(0)$ and $|e_{\theta_0}(x_i^+(0)) - \theta_i(0)| \leq \epsilon$, i.e., an $\epsilon$-accurate estimate is obtained when $\theta_i(0) \in S_i(0)$.

Theorem 6: Considering the distributed algorithm (2), under $I_i^I(0)$, the disclosure probability $\delta$ satisfies

$$\delta = \frac{\int_{S_i(0)} f_{\theta_0}(z)dz}{\int_{\mathcal{X}_i} f_{\theta_0}(z)dz}; \quad (20)$$

Specifically, if $\mathcal{X}_i = \mathcal{R}$, then

$$\delta = \max_{y \in \mathcal{R}} \int_{y-\epsilon}^{y+\epsilon} f_{\theta_0}(z)dz. \quad (21)$$

Proof: From (18) and the definition of $\delta$, we have

$$\delta = \Pr\{|\hat{x}_i^*(0) - x_i(0)| \leq \epsilon\}$$

$$= \Pr\{|\theta_i(0) - e_{\theta_0}(x_i^+(0))| \leq \epsilon\}$$

$$= \Pr\{\theta_i(0) \in S_i(0)\}$$

$$= \frac{\int_{S_i(0)} f_{\theta_0}(z)dz}{\int_{\mathcal{X}_i} f_{\theta_0}(z)dz}. \quad (22)$$

From Theorem 4, if $\mathcal{X}_i = \mathcal{R}$, then $e_{\theta_0}(x_i^+(0)) = e_{\theta_0}(0)$ which is independent of $x_i^+(0)$. In this case, we have

$$S_i(0) = \{\theta_i(0) \mid |e_{\theta_0}(0) - \theta_i(0)| \leq \epsilon\} = [e_{\theta_0}(0) - \epsilon, e_{\theta_0}(0) + \epsilon], \quad (23)$$
i.e., only if \( \theta_i(0) \in [e_{\theta_i(0)} - \epsilon, e_{\theta_i(0)} + \epsilon] \), we can obtain the \( \epsilon \)-accurate estimate of \( x_{i}(0) \). Then,

\[
\delta = \int_{S_i(0)} f_{\theta_i(0)}(z)dz = \int_{e_{\theta_i(0)} - \epsilon}^{e_{\theta_i(0)} + \epsilon} f_{\theta_i(0)}(z)dz.
\] (24)

Since \( e_{\theta_i(0)} \) satisfies (12), \( e_{\theta_i(0)} \) is the point \( y \) where \( f_{\theta_i(0)}(z) \) has the largest \( \epsilon \)-shaded area around the point \( y \), and the domain of \( y \) is \( R \), i.e.,

\[
e_{\theta_i(0)} = \arg \max_{y \in R} \int_{y - \epsilon}^{y + \epsilon} f_{\theta_i(0)}(z)dz.
\]

It follows that

\[
\delta = \int_{e_{\theta_i(0)} - \epsilon}^{e_{\theta_i(0)} + \epsilon} f_{\theta_i(0)}(z)dz = \max_{y \in R} \int_{y - \epsilon}^{y + \epsilon} f_{\theta_i(0)}(z)dz.
\] (25)

We thus have completed the proof.

A. Optimal Distributed Estimation Under \( I_1^j(1) \)

Under \( I_1^j(1) \), there are two outputs, \( x_{i}^+(0) \) and \( x_{j}^+(0) \), of node \( i \), which can be used for initial state estimation or inference attack. Note that \( x_{j}^+(0) = h_i(x_{i}^+(0), x_{j}^+(0) : j \in N_i) \), which means that \( x_{j}^+(0) \) has involved the outputs of node \( i \)'s neighbors. Hence, under \( I_1^j(1) \), both the optimal distributed estimation and privacy analysis depend on the output of both node \( i \) and its neighbor nodes. Suppose that \( h_i \) in (2) is available to the estimation in the remainder parts of this paper.

The following theorem provides the optimal distributed estimation of \( x_i(0) \) under \( I_1^j(1) \), which reveals the relationship between the information outputs (which are available to the node \( j \) for estimation) and the optimal estimation.

**Theorem 7:** Considering the distributed algorithm (2), under \( I_1^j(1) \), the optimal distributed estimation of \( x_i(0) \) satisfies

\[
\hat{x}_i^+(1) = x_i^+(0) - e_{\theta_i(0)} I_1^j(1)(x_i^+(0)),
\] (26)

where

\[
e_{\theta_i(0)} I_1^j(1)(x_i^+(0)) = \arg \max_{y \in [x_i^+(0) - x_i(0)]} \int_{y - \epsilon}^{y + \epsilon} f_{\theta_i(0)}(z)dz,
\] (27)

in which \( \hat{\theta}_i(1) = x_j^+(1) - h_i(x_i^+(0), x_j^+(0) : j \in N_i) \); Then, if \( N_i = R \), we have

\[
e_{\theta_i(0)} I_1^j(1)(x_i^+(0)) = \arg \max_{y \in R} \int_{y - \epsilon}^{y + \epsilon} f_{\theta_i(0)}(z)dz.
\] (28)

**Proof:** Let \( \hat{x}_i(1) \) be an estimate of \( x_i(0) \) under \( I_1(1) \) at iteration \( k = 1 \). Given \( T_v^\text{out}(1) \), and we have

\[
\Pr[T_v^\text{out}(1) = T_v^\text{out}(1)] = \Pr[T_v^\text{out}(1) = \{x_i^+(0), x_j^+(1)\} | x_i^+(0), x_j^+(1) \leq \epsilon, I_1(1)]
\]

\[
= \Pr[T_v^\text{out}(0) = x_i^+(0), T_v^\text{out}(0, 1) = x_j^+(1) | x_i^+(0), x_j^+(1) \leq \epsilon, I_1(1)]
\]

Note that \( x_i^+(0) \) depends on \( x_i(0) \) and \( \theta_i(0) \) only, while \( x_j^+(1) \) depends on \( x_i^+(0) \), \( x_j^+(0) : j \in N_i \) and \( \theta_i(0), \theta_j(0) \) are two random variables. It follows that

\[
\Pr[T_v^\text{out}(1) = \{x_i^+(0), x_j^+(1)\} | x_i^+(0), x_j^+(1) \leq \epsilon, I_1(1)]
\]

\[
= \Pr[T_v^\text{out}(0, 0) = x_i^+(0), T_v^\text{out}(0, 1) = x_j^+(1) | x_i^+(0), x_j^+(1) \leq \epsilon, I_1(1)]
\]

\[
\leq \int_{\hat{x}_i(1) - \epsilon}^{\hat{x}_i(1) + \epsilon} f_{\theta_i(0), \theta_i(1)}(x_i^+(0) - v, \hat{\theta}_i(1))dv,
\]

where

\[
\hat{\theta}_i(1) = x_j^+(1) - h_i(x_i^+(0), x_j^+(0) : j \in N_i).
\]
Using the relationship between the joint distribution and the conditional distribution, one infers that

\[
\int_{\tilde{x}_i(1)-\epsilon}^{\tilde{x}_i(1)+\epsilon} f_{\theta(0),\theta(1)}(x_i^+(0) - \nu, \tilde{\theta}_1(1))d\nu
= \int_{x_i^+(0) - \tilde{x}_i(1)-\epsilon}^{x_i^+(0) - \tilde{x}_i(1)+\epsilon} f_{\theta(1)}(\tilde{\theta}_1(1))f_{\theta(0)|\theta(1)}(z|\theta(1) = \tilde{\theta}_1(1))dz
= \int_{x_i^+(0) - \tilde{x}_i(1)-\epsilon}^{x_i^+(0) - \tilde{x}_i(1)+\epsilon} f_{\theta(1)}(\tilde{\theta}_1(1))f_{\theta(0)|\theta(1) = \tilde{\theta}_1(1)}(z)dz
\]

where \( f_{\theta(0)|\theta(1) = \tilde{\theta}_1(1)} \) is the conditional PDF of \( \theta(0) \) under the condition \( \theta(1) = \tilde{\theta}_1(1) \). Then, one can obtain that

\[
\begin{align*}
\max_{\tilde{x}_i \in \mathcal{X}_i} \Pr \left\{ T^\text{out}_1(k) > T^\text{out}_1(k) \right\} & = \max_{\tilde{x}_i \in \mathcal{X}_i} \int_{x_i^+(0) - \tilde{x}_i(1)-\epsilon}^{x_i^+(0) - \tilde{x}_i(1)+\epsilon} f_{\theta(1)}(\tilde{\theta}_1(1))f_{\theta(0)|\theta(1) = \tilde{\theta}_1(1)}(z)dz. \\
& = \max_{\tilde{x}_i \in \mathcal{X}_i} \int_{x_i^+(0) - \tilde{x}_i(1)-\epsilon}^{x_i^+(0) - \tilde{x}_i(1)+\epsilon} f_{\theta(1)}(\tilde{\theta}_1(1))f_{\theta(0)|\theta(1) = \tilde{\theta}_1(1)}(z)dz.
\end{align*}
\]

Hence, we have

\[
\hat{x}_i^+(1) = \arg \max_{\tilde{x}_i \in \mathcal{X}_i} \int_{x_i^+(0) - \tilde{x}_i(1)-\epsilon}^{x_i^+(0) - \tilde{x}_i(1)+\epsilon} f_{\theta(1)}(\tilde{\theta}_1(1))f_{\theta(0)|\theta(1) = \tilde{\theta}_1(1)}(z)dz
= x_i^+(0) - e_{\theta(0)|I_{j}^*(1)}(x_i^+(0)).
\]

When \( \mathcal{X}_i = \mathcal{R} \), we have \( x_i^+(0) - \mathcal{X}_i = \mathcal{R} \) hold for any output \( x_i^+(0) \in \mathcal{R} \). It follows that (27) is equivalent to (28) in this case. Thus, the proof is completed.

Note that the joint distribution of any two random variables \( X \) and \( Y \) satisfies

\[
f_{X,Y}(x,y) = f_{X|Y}(x|y)f_Y(y) = f_Y(x)f_X(y),
\]

and have we

\[
\int_{\tilde{x}_i(1)-\epsilon}^{\tilde{x}_i(1)+\epsilon} f_{\theta(0),\theta(1)}(x_i^+(0) - \nu, \tilde{\theta}_1(1))d\nu
= \int_{x_i^+(0) - \tilde{x}_i(1)-\epsilon}^{x_i^+(0) - \tilde{x}_i(1)+\epsilon} f_{\theta(1)}(\tilde{\theta}_1(1))f_{\theta(0)|\theta(1) = \tilde{\theta}_1(1)}(z)dz
= \int_{x_i^+(0) - \tilde{x}_i(1)-\epsilon}^{x_i^+(0) - \tilde{x}_i(1)+\epsilon} f_{\theta(1)}(\tilde{\theta}_1(1))f_{\theta(0)|\theta(1) = \tilde{\theta}_1(1)}(z)dz.
\]

It thus follows that \( e_{\theta(0)|I_{j}^*(1)}(x_i^+(0)) \) also satisfies

\[
e_{\theta(0)|I_{j}^*(1)}(x_i^+(0))
= \arg \max_{y \in \mathcal{R}} \int_{y-\epsilon}^{y+\epsilon} f_{\theta(1)|\theta(0)}(z)dz.
\]

It should be noticed that \( e_{\theta(0)|I_{j}^*(1)}(x_i^+(0)) \) can be viewed as the optimal distributed estimation of \( \theta(0) \) under \( I_{j}^*(1) \), which depends on the distributions of \( \theta(1) \) and \( \theta(0) \), the values of \( x_i^+(0) \) and \( \tilde{\theta}_1(1) \), and \( \mathcal{X}_i \). Next, we consider how these factors affect the value of \( e_{\theta(0)|I_{j}^*(1)}(x_i^+(0)) \).

For the results of Theorem 7, the noises being added at different time steps may or may not be independent to each other, which are examined in the following corollaries, respectively.

**Corollary 8:** Considering the distributed algorithm (2), if \( \theta(0) \) and \( \theta(1) \) are independent of each other, under \( I_{j}^*(1) \), we have \( e_{\theta(0)|I_{j}^*(1)}(x_i^+(0)) = e_{\theta(0)}(x_i^+(0)) \) and the optimal distributed estimation of \( x_i(0) \) satisfies

\[
\hat{x}_i^+(1) = \tilde{x}_i^+(0) = x_i^+(0) - e_{\theta(0)}(x_i^+(0)).
\]

**Proof:** For \( e_{\theta(0)|I_{j}^*(1)}(x_i^+(0)) \) in (26), since \( \theta(0) \) and \( \theta(1) \) are independent of each other, we have that

\[
f_{\theta(0)|I_{j}^*(1)}(\tilde{\theta}_1(1)\theta(0) = z) = f_{\theta(0)}(\tilde{\theta}_1(1))
\]

holds for \( \forall z \). Then, it follows from (32) that

\[
\int_{y-\epsilon}^{y+\epsilon} f_{\theta(0)}(\tilde{\theta}_1(1))f_{\theta(0)}(\theta(0) = z)dz
= \int_{y-\epsilon}^{y+\epsilon} f_{\theta(0)}(\tilde{\theta}_1(1))dz
= \int_{y-\epsilon}^{y+\epsilon} f_{\theta(0)}(\theta(0))dz,
\]

where \( f_{\theta(0)}(\tilde{\theta}_1(1)) \) is a constant when \( I_{j}^*(1) \) is fixed. Together with (27), one infers that

\[
e_{\theta(0)|I_{j}^*(1)}(x_i^+(0))
= \arg \max_{y \in \mathcal{R}} \int_{y-\epsilon}^{y+\epsilon} f_{\theta(0)}(\theta(0) = z)dz
= \arg \max_{y \in \mathcal{R}} \int_{y-\epsilon}^{y+\epsilon} f_{\theta(0)}(\theta(0))dz
= e_{\theta(0)}(x_i^+(0)),
\]

where we use the fact that \( f_{\theta(0)}(\tilde{\theta}_1(1)) \) is a constant under \( I_{j}^*(1) \). From Theorem 7, we have known that under \( I_{j}^*(1) \), \( \hat{x}_i^+(1) \) satisfies (26). Substituting (38) into (26), one obtains (35), which completes the proof.

The above corollary shows that when the added noises are independent of each other, the optimal distributed estimation \( e_{\theta(0)|I_{j}^*(1)}(x_i^+(0)) \) of \( \theta(0) \) at iteration \( k = 1 \) equals the optimal distributed estimation \( e_{\theta(0)}(x_i^+(0)) \) of \( \theta(0) \) at iteration \( k = 0 \), and thus we have \( \hat{x}_i^+(1) = \tilde{x}_i^+(0) \). Hence, one concludes that the later outputs cannot increase the estimation accuracy of \( x_i(0) \) when the added noises are independent of each other, and more details related to this conclusion will be provided in the next subsection.

Next, given \( \theta(0) \) and \( \theta(1) \) are dependent, we investigate how the different partial information of the topology and connectivity affect the optimal estimation of \( x_i(0) \), and obtain the following two corollaries.

**Corollary 9:** Considering the distributed algorithm (2), if \( N_i \subseteq N_j \) for \( \forall j \in N_i \) or the other nodes do not know all the information used for the updating by node \( i \), under \( I_{j}^*(1) \), the optimal distributed estimation of \( x_i(0) \) satisfies

\[
\hat{x}_i^+(1) = x_i^+(0) - \tilde{e}_{\theta(0)|I_{j}^*(1)}(x_i^+(0)),
\]

where \( \tilde{e}_{\theta(0)|I_{j}^*(1)}(x_i^+(0)) \) is the error term due to the dependency between \( \theta(0) \) and \( \theta(1) \).
where

\[ \hat{e}_{\hat{\Theta}(0)|I_j(1)}(x_i^+(0)) = \arg \max_{y \in \{x_i^+(0) - \lambda_i\}} \int_{y - \epsilon}^{y + \epsilon} \int_{\hat{\Theta}(0)|I_j(1)} f_{\hat{\Theta}(1)}(h) f_0(0|\hat{\Theta}(1) = h(z)) \, dz, \]

and \( \hat{\Theta}(0)|I_j(1) \) is the set of all possible values of \( \hat{\Theta}(1) \) under \( I_j(1) \). Specifically, if \( \hat{\Theta}(0)|I_j(1) \supseteq \Theta(1) \), we have

\[ \hat{e}_{\hat{\Theta}(0)|I_j(1)}(x_i^+(0)) = e_{\hat{\Theta}(0)}(x_i^+(0)) \]

and \( \hat{x}_i^+(1) = \hat{x}_i^+(0) \).

Proof: For \( \forall j \in N_i \), since \( N_i \subseteq N_j \), there is at least one neighbor node of node \( i \) satisfying \( l \in N_i \) but \( l \notin N_j \). It means that node \( j \) cannot obtain all the neighbor nodes’ information used for node \( i \)’s state updating. Thus, in the expression of \( \hat{\Theta}(1) \), there is at least one unknown variable in \( h_i(x_i^+(0), x_j^+(0): j \in N_i) \), which results in that the exact value of \( \hat{\Theta}(1) \) cannot be obtained. Hence, during the estimation, \( \hat{\Theta}(1) \) is no longer a deterministic value but is in a possible value set. Let \( \Theta(0)|I_j(1) \) be set of the all possible values of \( \hat{\Theta}(1) \) under \( I_j(1) \). During the estimation, we take all possible values of \( \hat{\Theta}(1) \) into consideration, and then obtain

\[
\Pr\{Z^\text{out}_{-i}(1) = \{x_i^+(0), x_j^+(0)\} \mid \forall |v - \hat{x}_i(1)| \leq \epsilon, I_j(1)\} = \int_{x_i^+(0)-\hat{x}_i(1)-\epsilon}^{x_i^+(0)-\hat{x}_i(1)+\epsilon} \int_{\hat{\Theta}(0)|I_j(1)} f_{\hat{\Theta}(1)}(h) \, dh \, f_0(0|\hat{\Theta}(1) = h(z)) \, dz.
\]

Therefore, we have

\[
\hat{x}_i^+(1) = \arg \max_{\hat{x}_i \in X_i} \Pr\{Z^\text{out}_{-i}(1) = \{x_i^+(0), x_j^+(0)\} \mid \forall |v - \hat{x}_i(1)| \leq \epsilon, I_j(1)\} = x_i^+(0) - \arg \max_{y \in \{x_i^+(0) - \lambda_i\}} \int_{y - \epsilon}^{y + \epsilon} \int_{\hat{\Theta}(0)|I_j(1)} f_{\hat{\Theta}(1)}(h) \, dh \, f_0(0|\hat{\Theta}(1) = h(z)) \, dz = x_i^+(0) - e_{\hat{\Theta}(0)}(x_i^+(0)).
\]

If \( \Theta(0)|I_j(1) \supseteq \Theta(1) \), we have

\[
\int_{y - \epsilon}^{y + \epsilon} \int_{\hat{\Theta}(0)|I_j(1)} f_{\hat{\Theta}(1)}(h) \, dh \, f_0(0|\hat{\Theta}(1) = h(z)) \, dz = \int_{y - \epsilon}^{y + \epsilon} \int_{\Theta(1)} f_{\hat{\Theta}(1)}(h) \, dh \, f_0(0|\hat{\Theta}(1) = h(z)) \, dz = \int_{y - \epsilon}^{y + \epsilon} f_0(0)(z) \, dz,
\]

where we have used the fact that

\[
\int_{\Theta(1)} f_{\hat{\Theta}(1)}(h) \, dh \equiv 1
\]

holds for \( \forall z \in \mathcal{R} \). It thus has

\[
\hat{e}_{\hat{\Theta}(0)|I_j(1)}(x_i^+(0)) = \arg \max_{y \in \{x_i^+(0) - \lambda_i\}} \int_{y - \epsilon}^{y + \epsilon} f_0(0)(z) \, dz = e_{\hat{\Theta}(0)}(x_i^+(0)),
\]

which means that

\[
\hat{x}_i^+(1) = x_i^+(0) - e_{\hat{\Theta}(0)}(x_i^+(0)) = \hat{x}_i^+(0).
\]

We thus have completed the proof.

In the above corollary, if the assumption that for an unknown variable, it can be any value in \( \mathcal{R} \) for estimation and \( h_i(x_i^+(0), x_j^+(0): j \in N_i) \) with domain \( \mathcal{R} \), then we have \( \Theta(0)|I_j(1) = \mathcal{R} \) since there is at least one unknown variable in \( h_i(x_i^+(0), x_j^+(0): j \in N_i) \). Then, (40) can be simplified to

\[ \hat{e}_{\hat{\Theta}(0)|I_j(1)}(x_i^+(0)) = \arg \max_{y \in \{x_i^+(0) - \lambda_i\}} \int_{y - \epsilon}^{y + \epsilon} f_{\hat{\Theta}(1)}(h) \, dh \, f_0(0|\hat{\Theta}(1) = h(z)) \, dz = \arg \max_{y \in \{x_i^+(0) - \lambda_i\}} \int_{y - \epsilon}^{y + \epsilon} f_0(0)(z) \, dz.
\]

where we have used the facts that (32) and

\[
\int_{\mathcal{R}} f_0(0|\hat{\Theta}(1) = h(z)) \, dh = 1.
\]

Corollary 10: Considering the distributed algorithm (2), if \( N_i \subseteq N_j \) and \( N_i \) are known to node \( j \), under \( I_j(1) \), the optimal distributed estimation of \( x_i(0) \) satisfies (26) with

\[ e_{\hat{\Theta}(0)|I_j(1)}(x_i^+(0)) = \arg \max_{y \in \mathcal{R}} \int_{y - \epsilon}^{y + \epsilon} f_{\hat{\Theta}(1)(1)}(h) \, dh \, f_0(0|\hat{\Theta}(1) = h(z)) \, dz.
\]

Proof: When \( N_i \subseteq N_j \) and \( N_i \) are known to node \( j \), under \( I_j(1) \), node \( j \) can obtain the exact value of \( \hat{\Theta}(1) \), since all the information of \( x_i^+(0) - h_i(x_i^+(0), x_j^+(0): j \in N_i) \) are available to it. That is, \( \hat{\Theta}(1) \) is fixed when node \( j \) makes the estimation, and thus

\[
\arg \max_{y \in \{x_i^+(0) - \lambda_i\}} \int_{y - \epsilon}^{y + \epsilon} f_{\hat{\Theta}(1)(1)}(h) \, dh \, f_0(0|\hat{\Theta}(1) = h(z)) \, dz = \arg \max_{y \in \{x_i^+(0) - \lambda_i\}} \int_{y - \epsilon}^{y + \epsilon} f_0(0)(z) \, dz.
\]

Then, from Theorem 7, we can obtain the results given in this corollary, which has completed the proof.

Corollaries 9 and 10 show the optimal distributed estimation of \( x_i(0) \) until iteration \( k \), considering node \( j \) can and cannot have all information of the parameters in \( h_i(x_i^+(0), x_j^+(0): j \in N_i) \) for the estimation, respectively. Therefore, they reveal that how the neighbor nodes’ information outputs affect the optimal distributed estimation according to the iteration process of the privacy-preserving distributed algorithm (2).

B. Optimal Distributed Estimation Under \( I_j(k) \)

In this subsection, we consider the optimal distributed estimation of \( x_i(0) \) under \( I_j(k) \). Let \( k \to \infty \), and we obtain the optimal distributed estimation under \( I_j(\infty) \).

We first give the following theorem, which provides the expression of the optimal distributed estimation under \( I_j(k) \).

Theorem 11: Considering the distributed algorithm (2), under \( I_j(k) \), the optimal distributed estimation of \( x_i(0) \) satisfies

\[ \hat{x}_i^+(k) = x_i^+(0) - e_{\hat{\Theta}(0)|I_j(k)}(x_i^+(0)), \]

where
where
\[
e_{\theta_i(0)|I_j^e(k)}(x_i^+(0)) = \arg \max_{y \in \{x_i^+(0)-\varepsilon, x_i^+(0)+\varepsilon\}} \int_{y-\varepsilon}^{y+\varepsilon} f_{\theta_i(1),\ldots,\theta_i(k)}(\tilde{\theta}_i(1), \ldots, \tilde{\theta}_i(k)) f_{\theta_i(0)|\theta_i(0)=\theta_i(1), \ldots, \theta_i(k)}(z) dz,
\]
in which \(\tilde{\theta}_i(k) = x_i^+(k) - h_i(x_i^+(k-1), x_j^+(k-1) : j \in N_i)\).

**Proof:** From Theorem 7, it is proved that (43) holds for \(k = 1\). Now, we prove that it holds for \(\forall k \geq 1\), where the basic idea is similar to the proof of Theorem 7.

Let \(\hat{x}_i(k)\) be an estimate of \(x_i(0)\) under \(I_j^e(k)\). We have the following equation holds,
\[
\Pr \{ T_{\text{out}}^e(k) = T_{\text{out}}^e(k) | \forall |v-x_i(k)\leq \epsilon, I_j^e(k) \} = \Pr \{ T_{\text{out}}^e(k) = \{x_i^+(0), \ldots, x_i^+(k)\} | \forall |v-x_i(k)\leq \epsilon, I_j^e(k) \}
\]
\[
= \Pr \{ T_{\text{out}}^e(k) = x_i^+(0), \ldots, T_{\text{out}}^e(k) = x_i^+(k) | \forall |v-x_i(k)\leq \epsilon, I_j^e(k) \}
\]
\[
= \int_{\tilde{\theta}_i(k)-\epsilon}^{\tilde{\theta}_i(k)+\epsilon} f_{\theta_i(0),\ldots,\theta_i(k)}(x_i^+(0)-v, \tilde{\theta}_i(1), \ldots, \tilde{\theta}_i(k)) dv,
\]
where \(\tilde{\theta}_i(k) = x_i^+(k) - h_i(x_i^+(k-1), x_j^+(k-1) : j \in N_i)\).

Using the properties of the joint distribution of multiple random variables, one infers that
\[
\int_{\tilde{\theta}_i(k)-\epsilon}^{\tilde{\theta}_i(k)+\epsilon} f_{\theta_i(0),\ldots,\theta_i(k)}(x_i^+(0)-v, \tilde{\theta}_i(1), \ldots, \tilde{\theta}_i(k)) dv
\]
\[
= \int_{x_i^+(0)-\tilde{\theta}_i(k)-\epsilon}^{x_i^+(0)-\tilde{\theta}_i(k)+\epsilon} f_{\theta_i(0),\ldots,\theta_i(k)}(\tilde{\theta}_i(1), \ldots, \tilde{\theta}_i(k)) f_{\theta_i(0)}(\tilde{\theta}_i(1), \ldots, \tilde{\theta}_i(k)) dz
\]
\[
= \int_{x_i^+(0)-\tilde{\theta}_i(k)-\epsilon}^{x_i^+(0)-\tilde{\theta}_i(k)+\epsilon} f_{\theta_i(0),\ldots,\theta_i(k)}(\tilde{\theta}_i(1), \ldots, \tilde{\theta}_i(k)) dz
\]
\[
\int_{\tilde{\theta}_i(0)|\theta_i(0)=\theta_i(1), \ldots, \theta_i(k)}(z) dz,
\]
which completes the proof.

**Corollary 12:** Considering the distributed algorithm (2), if the added noises \(\theta_i(0), \ldots, \theta_i(k)\) are independent of each other, under \(I_j^e(k)\), \(e_{\theta_i(0)|I_j^e(k)}(x_i^+(0)) = e_{\theta_i(0)}(x_i^+(0))\) and the optimal distributed estimation of \(x_i(0)\) satisfies
\[
\hat{x}_i^+(k) = x_i^+(0) - e_{\theta_i(0)}(x_i^+(0)).
\]

**Proof:** We only need to prove \(e_{\theta_i(0)|I_j^e(k)}(x_i^+(0)) = e_{\theta_i(0)}(x_i^+(0))\), then (47) can be inferred from Theorem 11 directly. Since the added noises are independent of each other, we have
\[
f_{\theta_i(0)|\theta_i(0)=\theta_i(1), \ldots, \theta_i(1)=\theta_i(1)}(z) = f_{\theta_i(0)}(z).
\]
Then, (44) can be simplified
\[
e_{\theta_i(0)|I_j^e(k)}(x_i^+(0)) = \arg \max_{y \in \{x_i^+(0)-\varepsilon, x_i^+(0)+\varepsilon\}} \int_{y-\varepsilon}^{y+\varepsilon} f_{\theta_i(1),\ldots,\theta_i(k)}(\tilde{\theta}_i(1), \ldots, \tilde{\theta}_i(k)) f_{\theta_i(0)}(\tilde{\theta}_i(1), \ldots, \tilde{\theta}_i(k)) dz
\]
\[
= e_{\theta_i(0)}(x_i^+(0)),
\]
which completes the proof.

One concludes from the above corollary that if the added noises sequence are independent of each other, the estimation accuracy of \(x_i(0)\) will not change with iteration \(k\) although there is more information available. It shows that the knowledge of data at following iterations cannot improve the estimate at iteration 0 when the noises are independent.

**Corollary 13:** Considering the distributed algorithm (2), if \(N_i \neq N_j\) for \(\forall i \in N_i\) or the other nodes do not know all the information used for the updating by node \(i\), under \(I_j^e(k)\), the optimal distributed estimation of \(x_i(0)\) satisfies
\[
\hat{x}_i^+(k) = x_i^+(0) - e_{\theta_i(0)|I_j^e(k)}(x_i^+(0)),
\]
where
\[
e_{\theta_i(0)|I_j^e(k)}(x_i^+(0)) = \arg \max_{y \in \{x_i^+(0)-\varepsilon, x_i^+(0)+\varepsilon\}} \int_{y-\varepsilon}^{y+\varepsilon} \int_{\theta_i(1),\ldots,\theta_i(k)}(z_k, \ldots, z_1) f_{\theta_i(0)|\theta_i(0)=\theta_i(1), \ldots, \theta_i(1)=\theta_i(1)}(z_0, \ldots, z_1) dz_k \cdots dz_1 dz_0.
\]

The \(\Theta_{\theta_i(k)|I_j^e(k)}\) is the set of all possible values of \(\tilde{\theta}_i(k)\) under \(I_j^e(k)\).

**Proof:** Similar to the proof of Corollary 9, if \(N_i \neq N_j\) for \(\forall j \in N_i\), there always exist unknown variables in the calculation of \(\tilde{\theta}_i(1), \ldots, \tilde{\theta}_i(k)\). Hence, under \(I_j^e(k)\), in (44), \(\tilde{\theta}_i(1), \ldots, \tilde{\theta}_i(k)\) cannot be fixed as constants during the estimation. Taking all the possible values of \(\tilde{\theta}_i(1), \ldots, \tilde{\theta}_i(k)\) into consideration for the estimation, (44) is written as (50).
When $\Theta_{i}(t)_{j}(t)^{\prime}(t) \supseteq \Theta_{\ell}$ holds for $\ell = 1, \ldots, k$, we have

$$
\int_{\Theta_{(i)}(t)} \cdots \int_{\Theta_{(i)}(t)} f_{\theta(1), \ldots, \theta(k)}(z_{k}, \ldots, z_{1})
$$

\begin{align*}
&= \int_{\Theta_{i}} \cdots \int_{\Theta_{i}} f_{\theta(1), \ldots, \theta(k)}(\theta_{0})
&\quad (z_{k}, \ldots, z_{1}|\theta_{0}) = z_{0}) dz_{k} \cdots dz_{1}
\end{align*}

$$
= \int_{\Theta_{i}} \cdots \int_{\Theta_{i}} f_{\theta(1), \ldots, \theta(k)}(\theta_{0})
\quad (z_{k}, \ldots, z_{1}|\theta_{0}) = z_{0}) dz_{k} \cdots dz_{1} \equiv 1,
\tag{51}
$$

holds for $\forall z_{0}$. It follows that

$$
\int_{y_{-\epsilon}}^{y_{+\epsilon}} \int_{y_{-\epsilon}}^{y_{+\epsilon}} \cdots \int_{y_{-\epsilon}}^{y_{+\epsilon}} f_{\theta(1), \ldots, \theta(k)}(z_{k}, \ldots, z_{1})
$$

\begin{align*}
&= \int_{y_{-\epsilon}}^{y_{+\epsilon}} \int_{y_{-\epsilon}}^{y_{+\epsilon}} \cdots \int_{y_{-\epsilon}}^{y_{+\epsilon}} f_{\theta(1)}(z_{0})
&\quad (z_{k}, \ldots, z_{1}|\theta_{0}) = z_{0}) dz_{k} \cdots dz_{1} dz_{0}
\end{align*}

$$
= \int_{y_{-\epsilon}}^{y_{+\epsilon}} f_{\theta(0)}(z_{0}) dz_{0}.
\tag{52}
$$

Thus, (40) is equivalent to

$$
\hat{e}_{\theta(0)}(t)^{\prime}(k)(x_{1}^{+}(0)) = \arg \max \int_{y_{-\epsilon}}^{y_{+\epsilon}} f_{\theta(0)}(z_{0}) dz_{0}
$$

$$
= \hat{e}_{\theta(0)}(t)(x_{1}^{+}(0)),
\tag{53}
$$

which completes the proof.

Note that if all the information used in (2) is available to node $j$ for estimation, then values of $\hat{\theta}_{j}(1), \ldots, \hat{\theta}_{j}(k)$ are fixed and known to node $j$. From Theorem 11, we obtain the following corollary directly.

**Corollary 14:** Considering the distributed algorithm (2), if $N_{i} \subseteq N_{j}$ and $N_{i}$ is known to node $j$, under $I_{j}^{i}(k)$, then the optimal distributed estimation of $x_{i}(0)$ satisfies (43) with

$$
e_{\theta(0)}(t)^{\prime}(k)(x_{1}^{+}(0)) = \arg \max \int_{y_{-\epsilon}}^{y_{+\epsilon}} f_{\theta(0)}(z_{0}) dz_{0}
$$

$$
= \hat{e}_{\theta(0)}(t)(x_{1}^{+}(0)).
\tag{54}
$$

The above three corollaries are correspondingly similar to Corollaries 8 to 10, respectively.

**Remark 15:** Corollary 13 gives the optimal estimation of $x_{i}(0)$ if other nodes do not know all the information used for the updating by node $i$. Note that the partial knowledge of the information used by node $i$ will not affect the result, i.e., $\hat{\xi}_{i}^{+}(1) = \hat{\xi}_{i}^{+}(0)$, so long as one variable in $h_{i}$ is unknown. However, it follows from Corollary 14 that if all information (including the global topology and the connectivity graph used during the iterative consensus process) about $h_{i}$ is known, the values of $\theta_{i}(1), \ldots, \theta_{i}(k)$ are released, and $e_{\theta(0)}(t)^{\prime}(k)(x_{1}^{+}(0))$ satisfies (54) and depends on $\theta_{i}(1), \ldots, \theta_{i}(k)$. Then, the estimation accuracy of $x_{i}(0)$ may be increased when the noise sequences $\theta_{i}(0), \ldots, \theta_{i}(k)$ are correlated with each other, since the relationship among the noise sequences can be used to decrease the uncertainty of noise $\theta_{i}(0)$ as shown in Theorem 18 of Sec. V-A.

**C. Disclosure Probability Under $I_{j}^{i}(k)$**

The information set that can ensure an accurate estimation is defined by

$$
S_{i}(k) = \{I_{j}^{i}(k) | e_{\theta(0)}(t)^{\prime}(k)(x_{1}^{+}(0)) - \theta_{i}(0) \leq \epsilon \}. \tag{55}
$$

Then, define $S_{i}^{k}(k)$ be the set of the first element in $S_{i}(k)$, i.e., all possible $x_{1}^{+}(0)$ included in $S_{i}(k)$.

$$
S_{i}^{k}(k) = \{\theta_{i}(0) | x_{1}^{+}(0) \in S_{i}^{k}(k)\}. \tag{56}
$$

Clearly, we have $S_{i}^{k}(k) = x_{j}(0) + S_{i}^{k}(k)$.

The following theorem provides an upper bounded of the disclosure probability under $I_{j}^{i}(k)$, which is denoted by $\delta(k)$.

**Theorem 16:** Considering the distributed algorithm (2), the disclosure probability $\delta$ at iteration $k$ satisfies

$$
\delta(k) \leq \int_{S_{i}^{k}(k)} f_{\theta(0)}(z) dz.
\tag{57}
$$

**Proof:** Given an $I_{j}^{i}(k)$, the optimal distributed estimation $\hat{x}_{i}^{+}(k)$ satisfies (43). Then,

$$
|\hat{x}_{i}^{+}(k) - x_{i}(0)| \leq \epsilon
$$

$$
\Leftrightarrow |x_{i}^{+}(0) - x_{i}(0) - e_{\theta(0)}(t)^{\prime}(k)(x_{1}^{+}(0))| \leq \epsilon
$$

$$
\Leftrightarrow |\theta_{i}(0) - e_{\theta(0)}(t)^{\prime}(k)(x_{1}^{+}(0))| \leq \epsilon.
\tag{58}
$$

From the definition of $\delta$, we have

$$
\delta(k) = \text{Pr}\{|\hat{x}_{i}^{+}(k) - x_{i}(0)| \leq \epsilon \}
$$

$$
= \text{Pr}\{|\theta_{i}(0) - e_{\theta(0)}(t)^{\prime}(k)(x_{1}^{+}(0))| \leq \epsilon \}
$$

$$
= \int_{S_{i}^{k}(k)} f_{I_{j}^{i}(k)}(z) dz,
\tag{59}
$$

where $f_{I_{j}^{i}(k)}(z)$ is the PDF of $I_{j}^{i}(k)$ (since $I_{j}^{i}(k)$ is random under the distributed algorithm). From the above function, it is hard to calculate the value of $\delta$, since $f_{I_{j}^{i}(k)}(z)$ is unknown and difficult to obtain due to the coupled input random variables. However, note that for each $I_{j}^{i}(k) \in S_{i}(k)$, its element $x_{1}^{+}(0)$ should satisfy $x_{i}^{+}(0) - x_{i}(0) = \theta_{i}(0)$ and $\theta_{i}(0) \in S_{i}^{k}(k)$. It means that only if $\theta_{i}(0) \in S_{i}^{k}(k)$,

$$
|\theta_{i}(0) - e_{\theta(0)}(t)^{\prime}(k)(x_{1}^{+}(0))| \leq \epsilon
$$

can be true. Thus,

$$
\delta(k) = \int_{S_{i}^{k}(k)} f_{\theta(0)}(z) dz
$$

$$
\leq \int_{S_{i}^{k}(k)} f_{\theta(0)}(z) dz,
\tag{60}
$$

which completes the proof.

If there exist other conditions for estimation, e.g., independent noise inputs, we obtain the closed-form expression of $\delta$, and thus we have the following theorem.

**Theorem 17:** Considering the distributed algorithm (2), under $I_{j}^{i}(k)$, if one of the following conditions holds:

1) the added noises $\theta_{i}(0), \ldots, \theta_{i}(k)$ are independent of each other;
2) $\Theta_{\hat{\theta}(0)(t)^{\prime}(t)} \supseteq \Theta_{\ell}$ or $\Theta_{\hat{\theta}(t)(t)^{\prime}(t)} = R$ holds for $\ell = 1, \ldots, k$ and $\forall k \geq 1$;

then $\delta(k) = \delta$ holds for $\forall k \geq 0$ and $\delta$ satisfies (20). Furthermore, if $X_{i} = R$, $\delta$ satisfies (21).
The above theorem can be obtained from Corollaries 12 and 13 and Theorem 6, so we omit the proof.

In the above subsections, all the theoretical results about the optimal distributed estimation and data privacy analysis can be extended to directed network topologies. The reason is that both the optimal distributed estimation \( \hat{x}_i(0) \) and the calculation of the disclosed probability \( \delta \) are based on the available information of node \( j \), and the bidirection communication is not necessary.

**Algorithm 1**: Calculation of \( e_{\theta(0)\theta(j)}(x_j^+(0)) \)

1. **Input**: The information \( I_j^f(k) \), the PDFs \( f_{\theta(0)}(z), \ldots, f_{\theta(j)}(z) \).
2. **Calculation**: Using the correlation among \( \theta_0(0), \ldots, \theta_j(k) \) to obtain joint PDF \( f_{\theta_0(0),\ldots,\theta_j(k)}(\hat{\theta}_1(1), \ldots, \hat{\theta}_j(k)) \) and the conditional PDF \( f_{\theta(0)\theta(j)}(\theta(k)=\hat{\theta}_j(k), \ldots, \theta_1(1)=\hat{\theta}_1(1)) \).
3. Computing the following derivative to obtain \( f_\theta(y, \epsilon) \),
   \[
   \frac{\partial}{\partial y} \int_{y-\epsilon}^{y+\epsilon} f_\theta(z)dz = F_\theta(y, \epsilon) \tag{61}
   \]
   where \( \hat{f}_\theta(z) = f_{\theta_0(1),\ldots,\theta_j(k)}(\hat{\theta}_1(1), \ldots, \hat{\theta}_j(k)) \).
4. Solving the following equation to obtain the zero point set, \( \Omega_{F_\theta}^0 \),
   \[
   F_\theta(y, \epsilon) = 0. \tag{63}
   \]
5. Calculating the set of \( \mathcal{X}_j^+(0) = [x_i^+(0) - \mathcal{X}_i] \cap \Omega_{F_\theta}^0 \cup [x_i^+(0) - \mathcal{X}_i] \).
6. Obtaining the estimation by
   \[
   e_{\theta(0)\theta(j)}(x_j^+(0)) = \arg\max_{y \in \mathcal{X}_j^+(0)} \int_{y-\epsilon}^{y+\epsilon} \hat{f}_\theta(z)dz. \tag{64}
   \]
7. **Output**: The estimation of \( e_{\theta(0)\theta(j)}(x_j^+(0)) \).

**D. Calculation of the Optimal Estimation**

From the discussions in the above subsections, the optimal distributed estimation of \( x_i(0) \) is the most important factor for the privacy analysis. We design an algorithm to calculate the optimal distributed estimation of \( x_i(0) \) under \( I_j^f(k) \) for \( \forall k \geq 0 \). From Theorem 11, one infers that the key challenge to obtain \( \hat{x}_i(k) \) is to calculate \( e_{\theta(0)\theta(j)}(x_j^+(0)) \). Similar to the general approach given in Sec. III-A, we design Algorithm 1 to calculate \( e_{\theta(0)\theta(j)}(x_j^+(0)) \).

**V. CASE STUDIES AND OPTIMAL NOISES**

Privacy-preserving average consensus algorithm (PACA) is a typical privacy-preserving distributed algorithm, which aims to guarantee that the privacy of the initial state is preserved and at the same time the average consensus can still be achieved [16], [18], [20]. The basic idea of PACA is adding and subtracting variance decaying and zero-sum random noises to the traditional consensus process. Regarding to privacy-preserving average consensus, the often used criterion in the literature is differential privacy. However, first, no matter what type of noise distribution is used, there is a chance that an estimated value of the original data is close to the real data, but such a probability cannot be directly measured by differential privacy (e.g., considering \( \epsilon \)-accurate estimate, the disclosed probability of initial states cannot be measured by differential privacy). Furthermore, [18] has proved that average consensus and differential privacy cannot be guaranteed simultaneously by PACA. Hence, it motivates us to provide the privacy analysis of PACA in terms of \( (\epsilon, \delta) \)-data-privacy in this section. We adopt the developed theories in the above section to analyze the \( (\epsilon, \delta) \)-data-privacy of the PACA algorithm, and then find the optimal noise for the algorithm to achieve the highest data privacy.

**A. Privacy of PACA**

Referring to the existing algorithms, we describe the PACA algorithm as follows:

\[
\begin{align*}
x(k+1) &= g_i(x_i^+(k), x_j^+(k) : j \in N_i) \\
&= w_{ii}(x_i(k) + \theta_i(k)) + \sum_{j \in N_i} w_{ij}(x_j(k) + \theta_j(k)),
\end{align*}
\]

for \( \forall i \in V \) and \( k \geq 0 \), where \( w_{ii} \) and \( w_{ij} \) are weights, and its matrix form is given by

\[
x(k+1) = W(x(k) + \theta(k)), \quad k \geq 0,
\]

where \( W \geq 0 \in \mathbb{R}^{n \times n} \) is a doubly stochastic matrix satisfying \( w_{ii} > 0 \) and \( w_{ij} > 0 \) for \( (i, j) \in E \) and \( w_{ij} = 0 \) for otherwise; and each \( \theta_i(k) \in \theta_i(k) \) satisfies \( \text{Var} \theta_i(k) < \rho \text{Var} \theta_i(k-1) \) (where \( 0 < \rho < 1 \)) and \( \sum_{k=0}^{\infty} \theta_i(k) = 0 \). When \( \theta(k) = 0 \) for \( k \geq 0 \), it is proved in [25] that an average consensus is achieved by (66), i.e.,

\[
\lim_{k \to \infty} x(k) = \frac{\sum_{k=1}^{n} x_t(0)}{n} = \bar{x}.
\]

When \( \theta(k) \neq 0 \) for \( k \geq 0 \), it is proved in [20] that an average consensus is achieved by (66) in the mean-square sense.

The following two theorems analyze the data privacy of the PACA algorithm under the conditions that node \( j \) can and cannot have all the information used in the iteration process for the estimation, respectively.

**Theorem 18**: If \( N_i \subseteq N_j \) and \( N_i \) is known to node \( j \) for \( j \in N_i \), using PACA, we have \( \delta = 1 \) holds for \( \forall \epsilon > 0 \), i.e., \( x_i(0) \) is perfectly inferred.

**Proof**: When \( N_i \subseteq N_j \) and \( N_i \) is known to node \( j \) for \( j \in N_i \), then the values of \( \hat{\theta}_1(1), \ldots, \hat{\theta}_i(\infty) \) are fixed and released to node \( j \) under \( I_j^f(\infty) \). From Corollary 14,
\begin{align}
&\epsilon_{\theta_i(0)}(x_i^+(0)) \\
&= \arg \max_{y \in [x_i^-(0)-x_i]} \int_{y-\epsilon}^{y+\epsilon} f_{\theta_i(0)}(y) \, dz.
\end{align}

(68)

Meanwhile, from \(\sum_{k=0}^{\infty} \theta_i(k) = 0\), it follows that \(\theta_i(0) = -\sum_{k=1}^{\infty} \theta_i(k)\). Hence, in the right side of (68), the maximum value of the integral is achieved when \(y = -\sum_{k=1}^{\infty} \theta_i(k)\), i.e.,

\(\epsilon_{\theta_i(0)}(x_i^+(0)) = -\sum_{k=1}^{\infty} \theta_i(k) = \theta_i(0)\).

Then, we have

\[x_i^+(\infty) = x_i(0) - \epsilon_{\theta_i(0)}(x_i^+(0)) = x_i(0),\]

i.e., \(x_i(0)\) is perfectly inferred, and thus \(\delta = 1\).

In the above proof, Corollary 14 is adopted to prove the theorem. Actually, if \(\tilde{\theta}_i(1), \ldots, \tilde{\theta}_i(\infty)\) are fixed and released, the values of \(\theta_i(1), \ldots, \theta_i(\infty)\) are released to node \(j\). Then, using the condition \(\sum_{k=0}^{\infty} \theta_i(k) = 0\), we can obtain \(\theta_i(0)\), and thus \(x_i(0)\) is obtained from using \(x_i^+(0) - \theta_i(0) = x_i(0)\).

Theorem 19: If \(N_i \subseteq N_j\) for \(\forall j \in N_i\) and \(\Theta_j(k) = \mathbb{R}\) for \(\forall i \in V\), then the PACA algorithm achieves \((\epsilon, \delta)\)-data-privacy, where \(\delta\) satisfies (20), and then if \(X_i = \mathbb{R}\), \(\delta\) satisfies (21).

Proof: Since the conclusion in this theorem are the same as Theorem 17, we prove it by showing that one of the conditions in Theorem 17 holds. Since \(N_i \subseteq N_j\) for \(\forall j \in N_i\), which means that any neighbor node \(j\) cannot obtain all the information using in the right-hand side of (65) at each iteration \(k\). Hence, there exists at least one \(x_{j_0}(k-1)\) \((j_0 \neq j\) and \(j_0 \in N_i)\) which is not available to node \(j\) for estimation. Note that under the PACA algorithm,

\[\tilde{\theta}_i(k) = x_i^+(k) - (w_{ij}x_i^+(k-1) + \sum_{j \in N_i} w_{ij}x_j^+(k-1)).\]

Since \(x_{j_0}^+(k-1) = x_{j_0}(k-1) + \theta_{j_0}(k-1)\) and \(\theta_{j_0}(k-1) \in \Theta_{j_0}(k-1) = \mathbb{R}\), we have \(\tilde{\theta}_i(k) \in \mathbb{R}\) during the estimation, i.e., \(\Theta_{\tilde{\theta}_i(k)}(x_i^+(k)) = \mathbb{R}\). Therefore, the second condition in Theorem 17 holds, and we thus have completed the proof.

With the above theorem, it is not difficult to prove that the algorithms proposed in both [6] and [20] provide \((\epsilon, \delta)\)-data-privacy and \(\delta\) satisfies (21).

Remark 20: From the above two theorems, on one hand, one infers that if all the information of one node used in the iteration process of the PACA is known to others for the estimation, \(x_i(0)\) can be perfectly inferred. On the other hand, the partial knowledge of the information used by node \(i\) will not affect the privacy result of the PACA, i.e., \(\delta\) satisfies (21), so long as one variable in \(h_i\) is unknown and with domain \(\mathbb{R}\).

B. Optimal Noises

In this subsection, we consider the optimization problem (8).

First, we investigate the necessary and sufficient condition that ensures an exact average consensus can be achieved through (66), and obtain a theorem as follows.

Theorem 21: Using the iteration algorithm (66), we can have (67) iff \(\lim_{k \to \infty} \sum_{l=1}^{k+1} W^l \theta(k-l+1) = 0\). Especially, if (67) holds, then \(\sum_{k=0}^{\infty} \sum_{i=1}^{n} \theta_i(k) = 0\).

Proof: From (66), it follows that

\[x(k+1) = W^{k+1}x(0) + \sum_{l=1}^{k+1} W^l \theta(k-l+1).\]

(69)

Since \(W\) is a doubly stochastic matrix, it is well known that \(\lim_{k \to \infty} W^{k+1}x(0) = \tilde{x}\). Taking limits on both sides of (69), we have

\[\lim_{k \to \infty} x(k+1) = \tilde{x} + \lim_{k \to \infty} \sum_{l=1}^{k+1} W^l \theta(k-l+1).\]

(70)

Thus, it follows that

\[\lim_{k \to \infty} \sum_{l=1}^{k+1} W^l \theta(k-l+1) = 0.\]

(71)

Then, one infers that

\[1^T \lim_{k \to \infty} \sum_{l=1}^{k+1} W^l \theta(k-l+1) = 0.\]

(72)

where we have used the fact that \(1^TW = 1^T\).

From the above theorem, one infers that if the noise adding process given in PACA satisfies the zero-sum condition and the series \(\sum_{l=1}^{k+1} W^l \theta(k-l+1)\) converge, then an exact average consensus can be achieved by the algorithm. Therefore, in PACA, the noise adding process is that each node \(i\) arbitrary chooses an integer \(k_i > 1\) and let \(\sum_{l=1}^{k_i+1} \theta_l(k) = -\theta_i(0)\), so the average consensus can be guaranteed. In other word, it is not difficult to satisfy the constraint in (8) using the above design in PACA, where there are not any constraints on the noise \(\theta_i(0)\).

Second, from Theorem 19, it follows that \(\delta\) satisfies (20), when node \(j\) cannot know all the information used in the consensus process at each iteration. Thus, using appropriate design of PACA, problem (8) can be considered as an unconstrained minimization problem as follows,

\[
\min_{f_{\theta_i(0)}(y)} \delta = \int_{S_i(0)} f_{\theta_i(0)}(y) \, dy.
\]

(72)

In problem (72), there is no constraint on \(f_{\theta_i(0)}(y)\) and it can be a PDF of any distribution of noises. Hence, we can find a \(f_{\theta_i(0)}(y)\) with a large variance such that \(\delta\) is smaller than any given small value since \(S_i(0)\) is a bounded set. For example, when \(X_i = \mathbb{R}\), we have \(S_i(0) = [\epsilon_{\theta_i(0)} - \epsilon, \epsilon_{\theta_i(0)} + \epsilon]\). Then, a uniform distribution with \(f_{\theta_i(0)}(y) \leq \frac{1}{M}\) \((M\) is a constant) can ensure that

\[
\delta = \int_{S_i(0)} f_{\theta_i(0)}(y) \, dy \leq \frac{2\epsilon}{M}.
\]

(73)
It means that for any given $\delta$, we can always find a large $M$ to ensure that the above inequality holds. Hence, one concludes that, for any given small $\delta$, PACA can provide $(\epsilon, \delta)$-data-privacy by adding an uniformly distributed noise with $f_0(0)(y) \leq \frac{1}{2\epsilon}$, where $M \geq \frac{2\epsilon}{\delta^2}$. It has been proved that the convergence rate of PACA depends on $\max(\lambda_2^2, |\lambda_n|^2)$, where $\lambda$ is the decay factor of the noise variance, $\lambda_2$ and $\lambda_n$ are the second largest and the smallest eigenvalue of $W$, respectively [20]. Thus, the convergence rate of PACA will not be affected by the distribution of $\theta_i(0)$.

Note that a doubly stochastic matrix $W$ can be easily designed for an undirected network in a distributed way, e.g., using Metropolis weights [10]. Considering directed networks, the strongly connected topology is needed to ensure the convergence of PACA. In this case, a doubly stochastic matrix $W$ is not easy to design in a distributed way, since the column-stochastic is difficult to be guaranteed in directed networks (where the column-stochastic is crucial for the algorithm to converge to the exact average). Hence, to ensure an exact average consensus, the algorithm should be redesigned so that $\lim_{t \to \infty} \sum_{i=1}^{n} x_i(t) = \sum_{i=1}^{n} x_i(0)$ and $\sum_{k=0}^{\infty} \sum_{i=1}^{n} \theta_i(k) = 0$ hold, i.e., the sum of the nodes’ states will not change when the algorithm converges.

Then, we consider the case that the variance of $\theta_i(0)$ is a constant. Note that a smaller $\epsilon$ means a higher accuracy estimation. It means that when $\epsilon$ becomes smaller, the value of $\delta$ is more important for the privacy preservation. Hence, we define the optimal distribution in the sense of the data-privacy as follows.

**Definition 22:** We say $f_{\theta_i(0)}^{*}(y)$ is the optimal distribution of $\theta_i(0)$ for PACA. If, for any given distribution $f_{\theta_i(0)}(y)$, there exists an $\epsilon_1$ such that $\delta(f_{\theta_i(0)}^{*}(y), \epsilon) < \delta(f_{\theta_i(0)}(y), \epsilon)$ holds for all $\epsilon \in (0, \epsilon_1]$.

Based on Definition 22, we formulate the following minimization problem,

$$\min_{f_{\theta_i(0)}(y)} \delta$$

s.t. $\text{Var}(|\theta_i(0)|) = \sigma^2.$ \hspace{1cm} (74)

From our previous research on this optimization problem [26], the optimal solution is that the noise $\theta_i(0)$ should follow a uniform distribution given $\epsilon \leq \sigma$.

Then, using the proposed theoretical framework in this paper, we conduct the simulation to compare the privacy of existing PACA. Figure 3 compares the $(\epsilon, \delta)$-data-privacy of PACA with normal distributed, uniformly distributed [20], and Laplace distributed [18] noise adding processes, respectively. In the simulation, 10,000 simulation runs are conducted, where one node first generates a state $\theta_i(0)$ randomly with the given distribution at each run. The other node uses the proposed optimal estimation approach to estimate the value of the noise $\theta_i(0)$ (i.e., $\hat{\theta}_i(0)$). Thus, one can obtain the disclosure probability of $\delta = |\theta_i(0) - \hat{\theta}_i(0)| \leq \epsilon$. Clearly, it is observed from Fig. 3 that uniform distribution is better than normal distribution and Laplace distribution in the sense of $(\epsilon, \delta)$-data-privacy.

**VI. Conclusions**

In this paper, we have investigated the optimal distributed estimation and privacy problem for privacy-preserving distributed algorithm. We introduced the definition of the optimal distributed estimation and the $(\epsilon, \delta)$-data-privacy definition, which reveals the relationship between the privacy and the estimation accuracy. A theoretical framework was provided for the optimal distributed estimation and the privacy analysis, where both the closed-form expressions of the optimal distributed estimation and the privacy parameters were obtained. With the obtained framework, we proved that the existing PACA algorithm is $(\epsilon, \delta)$-data-private and the optimal noises, which guarantees the minimized disclosure probability, was obtained. The applications of the proposed framework will be considered in our future work.

Lin Cai (S’00–M’06–SM’10) received her M.A.Sc. and PhD degrees in electrical and computer engineering from the University of Waterloo, Waterloo, Canada, in 2002 and 2005, respectively. Since 2005, she has been with the Department of Electrical & Computer Engineering at the University of Victoria, Canada, and she is currently a Professor.

Her research interests span several areas in communications and networking, including wireless sensor networks and emerging multimedia traffic over wireless, mobile, ad hoc, and sensor networks. She has served as a Technical Program Chair for IEEE Globecom’10 and Globecom’13. She has served as a member of the Steering Committee of the IEEE Transactions on Big Data, an Associate Editor of the IEEE Transactions on Vehicular Technology, EURASIP Journal on Wireless Communications and Networking, International Journal of Sensor Networks, and Journal of Communications and Networks (JCN), and as the Distinguished Lecturer of the IEEE VTS Society. She was a recipient of the NSERC Discovery Accelerator Supplement Grants in 2010 and 2015, respectively, and the Best Paper Awards of IEEE ICC 2008 and IEEE WCNC 2011. She has founded and chaired IEEE Vehicular Technology Conference, China and Communications Joint Societies Chapter. She is a registered professional engineer of British Columbia, Canada.
